H. E. Twining, H. W. Szylejko, and R. A. Kern (*U.S. nav. med. Bull.*, 1945, 45, 479) treated 41 cases of Vincent's angina by penicillin, and found that the majority (29) were cured by one course of ten intramuscular injections of 20,000 units. The remainder were cured by a second similar course given a day later, or a total of 400,000 units. The average number of hospital days for the penicillin treatment was seven, compared with 23 for cases treated by all other methods.

TREATMENT OF ACUTE APPENDICITIS

A STUDY OF 480 CONSECUTIVE CASES

BY

ALEXANDER LYALL, M.D., Ch.M., F.R.F.P.S., F.R.C.S.Ed.

Surgeon, Greenock Royal Infirmary

Acute appendicitis is still a very serious problem in spite of widespread propaganda aimed at early treatment and the avoidance of purgation by well-meaning parents in cases of undiagnosed abdominal pain in children. The overall mortality appears to vary fairly widely in different clinics. Grey Turner (1943) gives his own mortality figures over a period of some years as 3.49%. The figures of Busch and Spivack (1940), Arnheim and Neuhof (1940), and Jennings *et al.* (1942) vary between 1.8 and 2.2%. Dennis *et al.* (1942), who reviewed the reports from a number of American clinics, found that the death rate varied between 2.3 and 6.3%, with an average of 4.12%. Jennings *et al.* (1942) published tables summarizing the mortality figures from various reviews and found that they varied from Lazzarini's (1937) of 12% to their own of 1.9%.

Since the beginning of 1943 up to the present—i.e., the middle of 1945—I have personally dealt with a total of 480 cases of acute appendicitis. During 1943 the cases were treated at Glasgow Royal Infirmary and at an E.M.S. hospital. Since the beginning of 1944 the cases included have been those which came under my care in Greenock Royal Infirmary. In this consecutive series there were two deaths—an overall mortality of well under 0.5%. The series comprises patients of all ages from 4 to 72, and thus represents a very mixed collection of appendicitis cases. It is proposed to discuss briefly the treatment of these cases in an attempt to evaluate the factors responsible for this low mortality figure.

Classification and Treatment

We have divided the cases into four groups. The general methods of treatment will be discussed with each group.

1. Acute Appendicitis without Peritonitis

Into this group fell cases where the appendix was congested but showed little or no fibrinous deposition on its surface. Most of these were admitted within 24 hours of the onset of illness. Histologically there was usually ulceration of a crypt and leucocytic infiltration in the submucosa extending into the deeper parts of the muscularis. The cases were those frequently called acute catarrhal appendicitis. Of our cases 177 belonged to this group. Appendicectomy was carried out in all of them. The mortality was *nil*, and there were no post-operative complications.

2. Acute Appendicitis with Local Peritonitis

In this group the length of illness varied from 12 to 72 hours. The appendix showed the varying stages of pathology from acute suppurative or phlegmonous inflammation up to gangrene. All of them had much fibrinous deposit on the peritoneal surface, with a varying quantity of turbid or sero-purulent fluid in the abdominal cavity.

This group comprised 188 cases. Early appendicectomy was carried out in all but two of them—one an elderly woman who showed evidence of marked cardiovascular degeneration, the other a young male subject who had a tuberculous pleural effusion. They were treated by the "delayed" method, and the omental mass around the inflamed appendix slowly decreased in size and disappeared. Delayed removal was not considered advisable in these cases. Care was taken in this group to mop up most of the free fluid in the abdomen, as a positive culture was got in two-thirds of the cases tested. In most of them the organism found was coliform in type, although a streptococcus was present in two. All were closed without drainage except two in which there was a marked oozing of blood from the appendix bed. In these a little packing was inserted and brought out through the lower end of the wound. In cases in which the free fluid is frankly sero-purulent we believe it is advisable to irrigate the tissues of the abdominal wall with acriflavine solution and then dust them with sulphanilamide powder. This should be done immediately after the peritoneum has been closed. In the more advanced cases in this group we also sprinkled sulphanilamide into the peritoneum.

In one case a residual abscess developed a week after the operation and was drained by the suprapubic route. There were 5 septic wounds, all of which cleared up without trouble. There were no deaths.

3. Acute Appendicitis with Spreading Peritonitis

In all but four of the 52 cases included in this group the appendix was ruptured. In every one of them there was evidence of spreading peritoneal inflammation at a distance from the appendix, with diffuse fibrinous deposition and pus formation. Mere reddening of the peritoneum was not by itself taken as indicative of peritonitis, as this was found in many of the cases included in the previous group. In 27 of the cases the patient was classified as "desperately ill" and the condition was accompanied by marked toxicity and some degree of paralytic ileus. Early rather than urgent operation was carried out in all these cases except one, which was treated by the "delayed" method. In the very ill cases intravenous therapy was started—at once in the case of adults, and during the operation in children, who were otherwise more readily upset by the procedure. In all these ill patients it was found that a few hours in the Fowler position and the parenteral administration of sulphanilamide not only made them more fit for operation but caused the inflammatory products to gather in the lower abdomen, from which they could be more readily removed. In four of the cases an immediate enterostomy was carried out because of advanced paralytic ileus. In a fifth this was required six days after the primary operation. The fistula closed in all these cases but one, in which it eventually closed after five months.

Gastric suction was used in all the cases in which post-operative vomiting and distension became pronounced. When this happened a Ryle tube was passed by the nasal route and aspiration carried out by a syringe every half-hour.

Sulphanilamide was freely used in this group, particularly locally, and will be discussed later in this article. All the cases but four were drained. In one of the latter a large abscess developed in the abdominal wound two weeks after the operation.

The only patient treated by the real "delayed" method was a young seaman who had been operated upon in mid-Atlantic. The ship's medical officer had failed to find the appendix, and closed the abdomen without drainage. When seen by us some days later the patient had a diffuse peritonitis. He was treated in the Fowler position, with sips of water and intramuscular sulphonamide. The tenderness slowly decreased and finally faded off into the right lower abdomen after five days.

In many of the cases in this group the patient had a few days of grave illness, during which great emphasis was placed upon intravenous sulphonamide therapy. After this a steady recovery was made. The mortality rate was *nil* in this group.

4. Appendiceal Abscess

In most cases the abscess lay in the pelvis or behind the caecum. In a few it was retro-ileal, and in one it lay completely enclosed in omentum, forming a mass which was freely movable in the abdomen. There were 63 cases in this group. All but five of them were operated upon at once, and of the latter two were drained after a few days because of signs of extension of the inflammatory process. Thus, only three were treated by the real "delayed" method. In all but four of the cases the appendix was removed at the time of operation. We agree with Arnheim and Neuhof (1940), who pointed out that it is preferable to remove the appendix in these cases, not only because it may remain a potentially infected focus in the abdomen but also because other abscesses may lie behind it and be opened only after it has been detached. When the pus had been swabbed from the cavity sulphanilamide powder was liberally shaken into it and a drainage tube left in position.

The patients in this group were on the whole not nearly so ill as in Group 3, and intravenous therapy was required much less often. The only two deaths in the whole series of cases occurred in this group. One was that of a child who died suddenly, a few hours after operation, of what looked like an acute oedema of the lungs. A necropsy was not allowed. The other was that of a man aged 35 who died of a recurrent pelvic abscess eight days after the original operation. This case and the mistake which led to this complication will be referred to later.

Special Points in Treatment

Before beginning the present series of cases I attempted to formulate the most frequent causes of death in acute appendicitis. The most early important cause appeared to be the practice of operating at once on very ill patients "as a last resort." Another, particularly in children, was post-operative bronchopneumonia, and this seemed to be at least partly attributable to the anaesthetic. After some days cellulitis of the abdominal wall and residual abscess became important causes of morbidity and mortality. It was then decided to pay particular attention to means which might conduce to the prevention of these complications. The following points in technique appeared to be of importance.

(a) Anaesthetic

Well over 80% of the anaesthetics given to the cases of this series were administered by house-surgeons. We believe that there is nothing more injurious to a seriously ill patient than a raw house-surgeon attempting to use one of the complicated series of tubes and dials which constitute a modern anaesthetic apparatus. My house-surgeons are therefore instructed in the method of giving open ether without chloroform, and this is the anaesthetic always used in cases of acute appendicitis. Recently the induction has been made more rapid and comfortable for the patient by the use of vinesthene mixture. In extremely ill cases nitrous oxide with light ether has been given. In ill patients ether tends to stimulate the heart, and, in children particularly, there is a stage immediately after the completion of the operation when this stimulant effect wears off and the tendency to cardiac collapse becomes marked. This is minimized by having the intravenous drip started before completing the operation and by administering enough plasma to keep the circulatory volume up to normal. A mild post-operative bronchitis has been common, and in some cases a basal pulmonary collapse has occurred. These chest complications were not serious, and in regard to the death already mentioned as being due to pulmonary oedema there was doubt whether this was primarily due to the heart or to the lungs. Immediately after the operation patients are instructed in deep-breathing exercises and in many cases are made to inhale carbogen frequently. It is our impression that this has definitely reduced chest complications.

(b) Fluid and Chloride Replacement

In all very ill patients an intravenous drip was set up—in adults at once and in young children while under the anaesthetic—and saline, glucose, and plasma were administered. In most of the cases the lower end of the internal saphenous vein was found to be the best site of administration, and, particularly in restless children, the application of a light plaster to the foot and ankle will allow the intravenous therapy to be continued for days on end. Where the patient is very collapsed it is often exceedingly difficult to run fluid into the saphenous, and in such a case a vein of the antecubital space is more suitable. The speed of administration is regulated according to the needs of the patient and the effect on his pulse. The danger of overloading the right heart appears to us to be much less in the shocked and dehydrated patient than is usually suggested; and it is very gratifying to bring a patient literally back to life by running one or two pints of fluid into his circulation at a fairly rapid rate. We cannot overstress the importance of intravenous therapy in these very ill cases of peritonitis, and we feel that this has played a most important part in the low mortality figures.

(c) Time of Operation

The "delayed" or Ochsner-Sherren method of treatment in the advanced but localized appendiceal inflammatory process is too well known to require elaboration. It is in the treatment of diffuse peritonitis that there is some difference of opinion. It is interesting to note in passing, as has been pointed out by Guerry and McCutchen (1942), that it was really with reference to this type of case that Ochsner's (1934) original description of the "delayed" treatment was given. To quote from his article on appendicitis:

> "The temperature was 104° F., the pulse 140, the abdomen enormously distended, and the features pinched. My experience with this and other similar cases has taught me that whenever I operated upon patients approximately in this condition the patient invariably died. Some years ago . . . I frequently operated upon patients in this condition as a last resort, thinking that this gave them the last chance of recovery. The majority of these patients recover if the delayed treatment is followed."

There has been abundant evidence of the truth of Ochsner's observation, although most authors do not differentiate very well between the localized and the diffuse type of peritoneal involvement. Coller and Potter (1934) reduced their mortality from 52 to 8.6% by the "delayed" treatment in this type of case. Davis and McLaughlin (1940) reduced theirs from 60 to 14%, and Guerry and McCutchen (1942) reported a mortality rate of 10.6% in 96 cases treated by immediate operation and one of only 1.4% in 139 cases treated by expectant means.

Where there is pus, free and unlocalized, in the peritoneal cavity it is surely a fundamental surgical principle that it should be mopped up as soon as possible and the suppurating focus dealt with. Thus we have preferred early operation in these cases but have waited for some hours with the patient in the Fowler position in order to allow the inflammatory products to settle in the pelvic region and the initiation of intravenous therapy. Our results have been very satisfactory, all of our 52 cases making uninterrupted recoveries. We must remember, however, that the use of sulphanilamide may have played an important part in the recovery of this type of case, as we shall see later.

(d) Abdominal Incision

We now use Battle's incision in all our appendicectomy cases. Our only exception to this rule has been where the gridiron approach has been more directly over an abscess. We have had no example of sepsis spreading up the rectus sheath, nor have we seen an incisional hernia follow its use. The abdominal contents can be better visualized and a "difficult" appendix removed more easily and with less tendency to break down protective adhesions than with any other incision we know. As it is unnecessary to tear through muscular strata, and as the approach is a more direct one, there is less tendency to "pocketing" of pus in the abdominal wall than with the gridiron incision.

(e) Use of Sulphonamides

There is now much experimental and clinical work which proves the value of the sulphonamide group of drugs in the treatment and prevention of peritoneal infection. McGehee (1941) reported 401 cases of appendiceal perforation in which sulphanilamide had been used, with the low mortality figure of 6.2%. By the use of sulphonamides in the post-operative treatment of acute appendicitis in children Wattenberg and Heinbecker (1942) were able to reduce their mortality rate from 7.89 to 2.2%. Favourable results have also been reported by Thompson *et al.* (1941) and Stafford (1942).

The experimental work of Rosenburg and Wall (1941) and of Epps *et al.* (1942) in rats and dogs demonstrated that the mortality rate of peritonitis in these animals fell rapidly when sulphonamides were used. There is still some speculation as to which is the best individual sulphonamide compound to employ in peritonitis. Sulphanilamide powder appears to be the most popular local application, although sulphathiazole is preferred by many because of its greater potency in the usual peritoneal infections. Sutton (1942) has, however, reported adhesions following the use of this drug, a secondary intestinal obstruction actually developing in one case. This might be avoided by the suggestion of Epps *et al.* (1942) that a suspension of the drug would be more readily disseminated throughout the peritoneal cavity. Ambrose and Griswold (1942) found that sulphadiazine is absorbed from the peritoneum more slowly than either sulphanilamide or sulphathiazole, and Lyons and Burbank (1942) showed that sulphapyridine and sulphadiazine remained longer *in situ* than any of the other compounds. Gardiner (1944) obtained satisfactory results by using a suspension of sulphapyridine in saline, the rate of absorption from the peritoneum being very slow, and the drug still being present in the blood up to a week later.

Again, there is no unanimity as to the safe intraperitoneal dosage of the sulphonamides. Jackson and Coller (1942) found that after implanting 5 g. of sulphanilamide powder in the peritoneum the maximum blood concentration of nearly 10 mg. per 100 c.cm. was reached in about two hours. At 24 hours the level was less than 2 mg. per 100 c.cm. Hudson and Smith (1942), using an average of 15 g., found the peak concentration in the blood stream in about 12 hours, the figure falling to zero in 36 to 48 hours. Tashiro *et al.* (1942) pointed out that a blood concentration of 1 mg. per 100 c.cm. could be expected for every gramme of sulphanilamide placed in the peritoneum. Waugh *et al.* (1943) calculated that the systemic administration of the drug should be started 24 to 48 hours after the intraperitoneal administration of sulphanilamide and 3 to 4 days after sulphathiazole.

In our series the sulphonamides were considered to be unnecessary in the ordinary case of uncomplicated acute appendicitis. In the late suppurative stage they were sometimes used, and in the cases complicated by abscess or diffuse peritonitis their use was extensive. Sulphanilamide powder was employed. The powder is put up in double packets, each containing 5 g. and already sterilized, so that the surgeon has merely to lift out the inner packet after the nurse has torn off the top of the outer envelope. The dose varied between 5 and 10 g., depending upon the severity of the illness and the age of the patient. About two-thirds of the amount used was placed inside the abdomen and the remaining third in the tissues of the wound. After the pus had been swabbed from the abdomen the powder was simply "dumped" into the peritoneum, no great effort being made to disseminate it. Care was taken, however, to rub it evenly into all the corners of the wound. Particular care was taken to smear it abundantly round the track of the rubber drain, and it also seemed advisable to close the tissues snugly round the tube to minimize the escape of pus into the abdominal wall for at least the first few critical post-operative days until the raw tissues had acquired some immunity to infection. We also found it useful to spray the powder on to the stitched surface of the wound in order to protect it from escaping pus. In the very ill cases parenteral sulphonamide was started about 40 hours later, soluble sulphapyridine being given intravenously or sulphathiazole orally. The dosage was 1 g. four-hourly.

There was one important point in after-treatment which bitter experience taught us. In our earlier cases it was found that local application of the drug appeared in many cases to only temporarily subdue the infection which sometimes flared up into activity after four to six days. We thus learned to leave the drain in position longer than usual, and now allow it to be only very slowly shortened, so that it is not completely removed until the fifth or sixth day. We have already noted that one of our deaths was due to a residual pelvic abscess which flared up into activity a week after the primary operation. In this case the drain had been completely removed on the third day. Such a case is, of course, also an argument for the post-operative use of parenteral sulphonamide in all such conditions.

(f) Drainage of the Peritoneum

When a young surgeon removes a suppurating appendix and finds the peritoneum containing an abundant quantity of turbid almost frankly purulent fluid, his first inclination, on general surgical principles, is to drain the abdomen. To do this in such a case would be to disregard the excellent protective and reparative properties of the peritoneum. A very instructive experiment can be carried out by injecting a suspension of staphylococci into the peritoneum of a rabbit. Periodic examination of the peritoneal contents shows that there is an immediate phagocytic response, and within a few hours most of the organisms have been ingested by emigrating polymorphonuclear cells, the latter being afterwards phagocytosed by macrophages derived mainly from the serous lining. This suggests that where a peritoneal infection is not too overwhelming, and the focus of infection has been removed, the peritoneum may be allowed to look after itself. If we may be permitted to quote from Hilton's (1930) famous book, "Nature has a constant tendency to repair the injuries to which her structures have been subjected, whether these injuries be the result of fatigue or exhaustion, of inflammation or accident. Also this reparative power becomes at once most conspicuous when the disturbing cause has been removed."

Buchbinder *et al.* (1931) showed experimentally the fallacy of peritoneal drainage. They produced peritonitis in dogs by opening a loop of gut and leaving it for 24 hours. They then reopened the abdomen and closed the bowel. In the cases in which the abdomen was then drained the mortality was 100%. When closure was effected without drainage the mortality fell to 57.5%. Haggard and Kirtley (1940) quote Giertz, who found that, in cases of appendiceal peritonitis operated upon in the first 48 hours of illness, he was able to reduce the mortality from 22.2 to 3.5% by primary closure of the peritoneum.

In our series of cases, wherever possible, we refrained from draining the abdomen. We have followed the general principle that drainage is unnecessary when the appendix is unruptured, unless the peritonitis is obviously of advanced degree. The examination of peritoneal smears demonstrated the truth of this. In the early unperforated case the turbid fluid shows many polymorphonuclear leucocytes, some of which contain engulfed bacteria; only very occasionally are free bacteria found. In such a case it is obviously best to leave the peritoneum to combat the infection. As the condition progresses, however, the polymorphs become more degenerate and poorly stained, and the free bacteria more abundant. In frankly spreading peritonitis bacteria are abundant, most of the polymorphs are degenerating, and a piece of excised omentum shows stagnant and dilated blood vessels, many of which contain hyaline thrombi, and most of the lymphatic pathways are obviously blocked by fibrin thrombi. In such a one-sided struggle it is obviously safer to drain—not only to remove the products of bacterial activity but also to avoid abscess formation. In our past experience the main danger of peritoneal drainage has been the tendency to infection of the abdominal wall setting up a cellulitis. In the present series this danger appears to have been reduced to negligible proportions by the local use of sulphanilamide.

Conclusion

It is very difficult for any surgeon to evaluate properly the factors responsible for a decreasing morbidity and fatality rate in a series of cases such as this, particularly when this is a natural sequel to an increasing experience. In our series, however, the most important factors appear to have been the prompt use of intravenous therapy to restore fluid balance, and the intraperitoneal use of sulphanilamide powder.

Summary

A consecutive series of 480 cases of acute appendicitis with a mortality of under 0.5% is described. The main reasons for this low mortality are discussed.

My thanks are due to Mr. G. H. Stevenson and to Mr. W. A. Sewell, in whose wards I treated the early cases of this series; and particularly to my registrar, Mr. G. Russell Thomson, for his help and co-operation, without which the favourable results would have been impossible.

HEAVY NUPERCAINE SPINAL ANALGESIA IN OPERATIVE OBSTETRICS

WITH REPORT ON 394 CASES

BY

LOUIS RESNICK, M.B., Ch.B., M.R.C.O.G.

Whole-time Obstetrician and Gynaecologist, Hope Hospital, Salford

The safety of spinal analgesia in general surgery is recognized by most authorities nowadays. Its use in obstetrics, however, is still looked upon as a "risky" and even dangerous practice by the majority of obstetricians, in view of the occasional alarming drop in blood pressure, with its attendant dangers. In recent years a good deal of literature concerned with spinal analgesia in Caesarean section has appeared, among which may be mentioned reports by Brindeau (1935), Lloyd-Williams (1937), Murad and Parhad (1937), Cosgrove, Hall, and Gleeson (1937), Duca (1938), Pérez and Guglielmo (1939), Sebrechts (1940), and Weintraub and Merriam (1943).

The first recorded series of cases performed under heavy percaine (or nupercaine) spinal analgesia was that of Thomas (1942, 1944), who reported two series totalling 203 Caesarean sections, of which 200 were carried out under heavy percaine, without a maternal death due to that drug or a maternal death due to any cause whatever during its use.

In the past two years analgesia by the spinal route, using heavy nupercaine, has been the method of choice in the obstetrical department of this hospital for patients requiring Caesarean section and operative vaginal delivery. In this period spinal analgesia was given successfully on 394 occasions to 393 patients, 137 of whom had Caesarean section and 256 operative vaginal delivery. This paper is an analysis of the results in these cases, and an attempt to estimate the safety of heavy nupercaine in operative obstetric practice.

Solution Used.—Heavy nupercaine (Ciba Ltd., 1944) is the hyperbaric solution, 1 in 200, with 6% glucose, and is made up in sterile 3-c.cm. ampoules. It is a derivative of quinoline—the hydrochloride of α-butyloxycinchoninic acid diethylethylenediamide.

Premedication

In Caesarean Section.—(i) Cases not in labour, or in early labour, in which sedatives have not been given. Omnopon 1/3 gr. and scopolamine 1/300 gr. were administered about 45 minutes before operation. Atropine 1/100 gr. was given in all cases, in the event of the spinal analgesic not producing the desirable effect and a general anaesthetic becoming necessary. Ephedrine 1 gr. was given to all patients at the same time, to combat a drop in blood pressure. (ii) Cases of trial labour under twilight sleep, or cases in which other sedatives have been used. Atropine 1/100 gr., with ephedrine 1 gr., was given as a routine as in (i). Other supporting sedatives were not found necessary.

Cases requiring Operative Vaginal Delivery.—Supporting sedatives were rarely needed, as twilight sleep or other methods of sedation were prescribed in the majority of cases. Ephedrine 1 gr. was given to all patients half an hour before operation. We have often employed paraldehyde by the rectal route, in cases of severe pre-eclamptic toxaemia ("eclampsism") and cases of essential hypertension, in labour. In these no other supporting sedative was used when operative vaginal delivery was considered necessary. In one case of intra-partum eclampsia 6 dr. of paraldehyde in 4 oz. of olive oil was given as a routine. Delay in the second stage of labour occurred, and forceps extraction was indicated. Ether or chloroform anaesthesia was contraindicated owing to the presence of bronchitis after a recent attack of influenza. The paraldehyde acted as premedication to both the spinal puncture and the forceps extraction under spinal analgesia.

Technique of Administration of the Spinal Analgesic

In Cases requiring Caesarean Section.—The technique outlined by Thomas is clear enough to need little elaboration. The dosage we used was 1.2 to 1.5 c.cm., barbotage being part of the method.

In Patients requiring Operative Vaginal Delivery.—An important preliminary procedure in dealing with these cases was the reassurance of the patient immediately before the operation, as occasionally the mere movement of the woman during traction on the foetus, such as with forceps, caused her marked anxiety, although no real pain was experienced during the entire operation. The technique of administration was similar to that employed in Caesarean section, with a few variations. The Trendelenburg and lithotomy positions used after injection of the analgesic solution were found unnecessary here. The dosage employed was 0.5 to 0.8 c.cm., with barbotage. Analgesia reaching to just below the level of the umbilicus, including the pelvic floor and perineum, was obtained. In several cases the "sitting" posture was adopted, especially with extremely obese patients, in whom the spinal column was difficult to define, and with patients in whom spinal deformities existed. The subject is turned on to her back immediately after the introduction of the analgesic, as described above.

Analysis of the Cases

394 spinal analgesias were administered to 393 patients, 137 of whom had Caesarean section and 256 operative vaginal delivery. (One patient had two successful analgesias.) Patients requiring supplementary inhalational or intravenous anaesthesia were not included in this series.

Indications for Caesarean Section.—Table I summarizes the indications, the majority of which were provided by contracted pelvis, previous section, and disproportion. Included in this series were two patients with disproportion in whom unsuccessful attempts at forceps extraction had been made before admission to hospital. In 7 cases sterilization by the Madlener method was performed, and in one a large ventral hernia was repaired.

TABLE I.—*Indications for Caesarean Section*

Indication	Primigravidae	Multiparae	Total
Contracted pelvis	27	31*	58
Disproportion (including persistent occipito-posterior and transverse lies)	21	10	31
Placenta praevia	4	5	9
Foetal distress	8	—	8
Pre-eclamptic toxaemia	7	—	7
Bad obstetric history	—	5	5
Breech presentation (elderly primigravidae)	3	—	3
Essential hypertension (elderly primigravidae)	3	—	3
Accidental haemorrhage	2	—	2
Prolapse of the umbilical cord	2	—	2
Uterine inertia (elderly primigravidae) ..	2	—	2
Pelvic fibroid	2	—	2
Pelvic ovarian cyst	1	—	1
Ruptured uterus	—	1*	1
Chronic nephritis	1	—	1
Rigid cervix	1	—	1
Ruptured ovarian cyst	1	—	1
Total	85	52	137

* Previous Caesarean section.

Types of Operation.—Of the 137 operations performed 103 were lower uterine segment Caesarean sections (75.18%) and 34 were classic Caesarean sections (24.81%).

Indications for Operative Vaginal Delivery.—These are summarized in Table II. Delay in the second stage of labour was the main indication in 154 cases. There were 14 cases of "failed forceps"; these patients had had general anaesthetics before admission, and required operative delivery after treatment for shock. Destructive operations, such as craniotomy and perforation of the foetal head, were performed in 6 cases.

Methods of Delivery.—In 256 patients labour was terminated as follows: (i) *Low-forceps extraction* (136 cases): To one patient two spinal analgesias were administered—first for reposition of a prolapsed umbilical cord and the application of Willett's forceps, and five hours later for a low-forceps extraction. (ii) *Mid-forceps extraction* (108 cases). (iii) *High-forceps extraction* (8 cases): Three cases of hydrocephaly required perforation of the head before extraction. (iv) *Breech extraction* 6 cases. (v) *Craniotomy*, 4 cases. Of 262 infants delivered 167 required manual rotation of the foetal head, arrested in the transverse and posterior positions.

TABLE II.—*Indications for Operative Vaginal Delivery*

Indications	Booked Cases					Emergency Cases					Total

Grand total	196					66					262

Post-operative Complications

Headache.—In spite of the precautions taken over lumbar puncture, this complication was the most serious feature of spinal analgesia in this series. After Caesarean section there were 17 cases (12.4%) of headache—7 (5.1%) severe and requiring sedatives, and 10 (7.3%) slight and requiring little or no sedation. Of the patients undergoing operative vaginal delivery 39 (15.2%) complained of headache—9 (3.5%) severe and 30 (11.7%) slight. In the complete series of 393 patients, therefore, 56 cases of headache occurred (14.2%). During the same period heavy nupercaine analgesia was used in 306 gynaecological cases, the technique being the same, and an incidence of 6.65% headache was found. Spinal headache was therefore encountered slightly more than twice as often in parturient as in non-parturient women.

Chest Complications.—Basal collapse was encountered in only one case in the entire series—in a patient who had had a Caesarean section. Bronchitis occurred in 7 patients—one after Caesarean section and 6 after vaginal delivery. Sixteen of the latter group had had general anaesthetics before admission to hospital. Pneumonia was not encountered.

Late Results.—There were no complaints of headache, or other complications attributable to the analgesic, after discharge from hospital.

Maternal Mortality; Infant Mortality

(*a*) *After Caesarean Section.*—There were no deaths, immediate or remote, in the entire series of cases undergoing Caesarean section. (*b*) *After Operative Vaginal Delivery.*—Of 256 patients who were delivered by the vaginal route 2 died: the first, three days after forceps extraction, owing to aplastic anaemia following acute pyelitis treated with sulphonamides; the second, 16 days after delivery, owing to pulmonary embolism. The overall maternal mortality was therefore 0.50% in the 393 patients subjected to spinal analgesia, the deaths not being attributable to the analgesic.

Seven (5.1%) infants delivered by Caesarean section and 34 (13%) by operative vaginal route were lost. In no case was foetal death attributable to the analgesic.

Advantages of Heavy Nupercaine Anaesthesia

So far as Caesarean section is concerned nothing further can be added to the conclusions noted by Thomas in his paper "Caesarean Section under Spinal Analgesia"; these we confirmed.

In patients requiring operative vaginal delivery the advantages are:

To the Mother.—(i) Spinal analgesia is safe in patients with constitutional diseases which contraindicate general anaesthesia, such as chronic bronchitis, pulmonary tuberculosis, and chronic heart disease. (ii) It is safe in patients with types of liver and kidney impairment in which general anaesthesia may act adversely—e.g., pre-eclamptic toxaemia. (iii) It is safe in patients with essential hypertension. (iv) Uterine atony and undue uterine haemorrhage are rarely encountered in the third stage of labour. (v) Obstetric shock is rare. The spinal analgesic, acting as a regional nerve-block, cuts out reflex stimuli from the pelvis and perineum. This, associated with a lessened tendency to uterine haemorrhage, prevents the two chief factors which may produce obstetric shock. (vi) There is an absence of immediate post-operative discomfort and vomiting. The general condition of the patient, both during the operation and afterwards, is much better than after general anaesthesia. (vii) Pulmonary complications are rare.

To the Accoucheur.—(i) Spinal analgesics can be rapidly given, the technique being simple. (ii) Spinal analgesia makes it possible for the single-handed accoucheur to undertake manipulations or other treatment, in institutions suitably equipped. In the absence of a skilled anaesthetist the spinal analgesic may be given and the delivery performed by the accoucheur himself. This practice was carried out in every case in the series of 256 operative vaginal deliveries. (iii) Maximal relaxation of the pelvic musculature is obtained by the spinal analgesic, rendering intrapelvic manipulations, such as manual rotation of the foetal head arrested in the posterior or transverse positions, easier than under general anaesthesia. (iv) Additional anaesthesia is not required for the repair of an episiotomy or laceration.

To the Infant.—The analgesic has no detrimental effect whatever on the infant.

It is our opinion that spinal analgesia, using heavy nupercaine, is safe and reliable in operative obstetrics in selected cases of advanced pregnancy.

Contraindications to Spinal Analgesia

(i) Any disease of the central nervous system or of the vertebrae, or lumbro-sacral infection interfering with aseptic technique. (ii) In the presence of abnormal presentations, such as transverse lies, requiring internal or external version. (iii) A blood pressure below 100 mm. (iv) In acute shock. After the treatment for shock, spinal analgesia may be employed providing the blood pressure is over 100 mm. Hg. Spinal analgesia was used with striking success in 36 cases of acute shock, after routine shock treatment. (v) In acute heart failure from any cause. (vi) In the presence of "constriction ring dystocia." General anaesthesia was found to be essential in these cases to overcome uterine spasm.

Summary

Two series totalling 394 obstetrical cases, of which 137 were Caesarean sections and 257 operative vaginal deliveries under spinal analgesia, are presented. No maternal deaths attributable to the analgesic occurred.

Heavy nupercaine, 1 in 200, in 6% glucose, was employed in all cases.

The advantages, contraindications, and complications of spinal analgesia in operative obstetrics are outlined.

My thanks are due to Mr. George Brown, medical superintendent of this hospital, for permission to publish the results of these cases; and to the assistant obstetrical and medical officers, who administered several of the spinal analgesics for Caesarean section and who performed a number of the operations. I am particularly indebted to the midwifery staff for the excellent supervision and nursing care.

BLADDER-NECK OBSTRUCTION DUE TO NON-MALIGNANT DISEASE OF THE PROSTATE

BY

H. HAMILTON STEWART, M.A., M.B., B.Chir., F.R.C.S.

Honorary Surgeon, Bradford Royal Infirmary; Urological Surgeon, Bradford Municipal Hospital

There is no doubt that many patients suffering from prostatic obstruction come for treatment late in the progress of the disease. They delay until the kidneys are permanently damaged and secondary cardiovascular changes have occurred. Many lull themselves into complacency by believing that they suffer from "the old man's complaint," for which no treatment is necessary. Doctors are partly responsible for the delay. The diagnosis may be missed, or the seriousness of the condition be not realized. I constantly see cases with the history of acute retention relieved by catheterization. Surgical advice was not sought until further retention developed, and catheterization on this occasion failed. Renal damage occurred between the retentions, and catheterization merely postponed the evil day, so that in the end the patient faced the operation in a poor state of health.

Repeated catheterization in these cases of retention due to bladder-neck obstruction should, except in special cases, have no place in modern treatment. When the expectation of life, from other causes, is short, a trial, however, is justifiable. In a case of acute retention due to prostatic obstruction the wisest course is not to pass a catheter but to give a small dose of morphine and place the patient in the hands of the surgeon. If a urethral catheter has then to be passed it can be done with the most careful asepsis under the best conditions. Infection carried in by the passage of a catheter translates the patient at once to a less favourable class for treatment.

Many patients, and doctors themselves, view the possibility of suprapubic prostatectomy with horror, and delay treatment as a result. Many of its unpleasant features have been removed by the advent of the perurethral operation, but some doctors hesitate to advise that method because the view is current that the obstructing portion of tissue alone is removed. They feel it is only a matter of time before the remaining glandular tissue hypertrophies and further obstructive symptoms develop.

It would not appear to be generally known that perurethral prostatectomy when properly performed results in as complete a removal as suprapubic enucleation, and the prospect of recurrence is remote. "Resection" of prostatic tissue to leave a channel through which urine may pass should be the aim only in malignant cases. I believe that prostatectomy should be performed as soon as the diagnosis of prostatic obstruction is established unless coexisting diseases make the expectation of life short.

Symptoms and Physical Signs

When prostatic obstruction causes retention of urine the diagnosis is easy. When it causes sufficient trouble with micturition to bring the patient to the doctor the diagnosis is generally easy. There are cases, however, in which the urinary phenomena are so slight and their onset so gradual that the patients are unaware of anything wrong with the working of the bladder. These patients seek advice because of general symptoms such as dyspepsia, lack of power of concentration, lassitude, cardiovascular disease, abdominal discomfort, backache, haematuria, etc., and the condition of the bladder-neck obstruction is discovered on routine examination. Relatively young patients, with prostatic bars of fibrous and congenital origin particularly, come into this class.

These cases of silent obstruction can very easily be missed. Abdominal examination may reveal a distended bladder by palpation or percussion, but, on the other hand, the bladder dome may be intraperitoneal and intestine may lie in front of it. The diagnosis in several such cases has been suspected by their medical attendants on observing displacement upwards of the pelvic colon in radiographs taken for suspected gastric disorders.

I should like to emphasize the following method for the detection of such cases, and am of the opinion that they will not be missed if the physician or surgeon, in making his routine rectal examination, examines the patient in the three positions described below. The patient should pass urine before the examination.

First Position : Left Lateral.—The rectum is examined. Careful examination of the prostate is then made. Its size and consistency are noted, any irregularities on its surface discovered by light palpation or, if in the substance of the gland, by deep palpation, and any adhesion to or tethering of the rectal mucosa observed. One examines to discover if the median groove and lateral fornices are present, and, if so, their size. One observes if the upper notch can be palpated, and determines the size of the apices of the lobes.

Second Position : Knee-Chest.—The lumbar curve is exaggerated. The seminal vesicles are palpated and any perivesicular infiltration noted, whether neoplastic or fibrotic.

Third Position : Supine.—The legs are flexed and abducted. A bimanual examination through the rectum is then made. The position of the upper limit of the bladder may be detected by "ballottement," the impulse being transmitted to the rectal finger on the prostate. It is possible by this method to assess fairly accurately the amount of residual urine and the degree of hypertrophy of the bladder musculature.

Frequency by day or night, or both, may be present, and there may be "duplication" of micturition, particularly first thing in the morning. Intermission of the stream, a terminal dribble with a feeling of incomplete evacuation, and urgency are often symptoms. Pain at the beginning of or during the act of micturition may be felt by the patient at the end of the penis or "deep in the bladder-neck," and occasionally along the urethra. If terminal pain is present one should expect some coexisting lesion such as infection, new growth, or stone. Haematuria, initial or terminal, with the passage of clots, is not in my experience a very common symptom. If present one should assume that it is not primarily prostatic unless proved so. These cases require full investigation. The presence of pus in the urine, whether "sterile" or not, should always arouse suspicion. Sterile pus may be present in the urine in a case of uncomplicated prostatic obstruction. This may be due to trauma to the mucosa from overstretching, or from compression as a result of gross hypertrophy of the bladder musculature. It may, however, indicate, and often does, associated lesions such as a stone, growth, tuberculosis, etc. An infected urine in a patient who has never been catheterized should also make one suspicious.

Incontinence may be present, whether due to urgency or to lack of control. General symptoms noted are diminished powers of concentration, failure of memory for recent events, sense of fatigue, diurnal somnolence, loss of appetite, dyspepsia, constipation, dry and muddy skin.

Classification

For diagnostic purposes cases may be divided into three groups.

Group I.—Cases with prostatic symptoms, residual urine present, no neurological lesion, *x*-ray-negative. Hypertrophy of the bladder musculature usually develops as a result of prostatic obstruction. In this way the obstruction is at first overcome. The capacity of the bladder decreases. As the obstruction increases decompensation develops and residual urine is usually present.

Group II.—Cases with prostatic symptoms, no residual urine, no neurological lesion, *x*-ray-negative. These are cases in which compensation has been maintained and gross hypertrophy of the bladder musculature develops. Thus, although there may be a severe degree of bladder-neck obstruction, no residual urine is present. Aseptic pyuria quite often occurs in such cases as a result of trauma to the mucosa, and renal damage may be considerable. In these cases cystometric pressure readings reveal a hypertonic myogenic bladder. Cystograms show a contracted bladder with a crenellated outline. Intravenous urograms may demonstrate dilatation of the upper urinary tract, and kidney function tests show evidence of renal damage. Cystoscopic examination reveals trabeculation of the bladder musculature and direct-vision urethroscopy evidence of a bladder-neck obstruction.

Group III.—Atypical cases with symptoms and signs suggesting coexisting lesions of the urinary tract or central nervous system—e.g., recurrent urinary tract infection, aseptic pyuria, or haematuria. These cases require a very full urinary investigation, including, if necessary, catheterization of ureters for the purpose of obtaining specimens of urine from each kidney, and ascending anatomical pyelograms. Cystometric readings will help one to determine the degree of trouble due to prostatic obstruction when a coexisting tabetic lesion exists.

Clinical Method of Determining Size of Prostate Gland without Cysto-urethroscopy

The hazards of too frequent instrumentation in prostate cases must not be overlooked. The desire to carry out an inflexible routine of diagnostic study by the cysto-urethroscope in all cases before operation is contemplated may be scientifically correct, but will result in making many cases into unfavourable operative risks. It should therefore be avoided if possible. The ideal time for the cysto-urethroscopic examination is immediately before the perurethral prostatectomy, and, in those cases judged suitable for suprapubic prostatectomy this examination should not be performed at all unless they come under the heading of complicated cases (Group III). The cysto-urethroscopic examination, with catheterization of the ureters if necessary, should then be made as a set procedure, but could if need arose be followed immediately by a suprapubic drainage. It is my invariable practice, if a cysto-urethroscopic examination has been made and an obstructing prostate is present, to insert a Foley's catheter and not remove it until operation has relieved the obstruction.

As the type of operation to be performed is often determined by the size of the gland, it is important to be able to assess the size without cysto-urethroscopy. The bladder must be empty, so that residual urine does not interfere with the examination, which is best made at the time the residual urine is determined. The patient is examined in the supine position with the legs abducted and flexed. The right index finger is placed in the rectum on the prostate gland and the fingers of the left hand palpate the lower abdomen. On relaxation of the abdominal wall the fingers sink into the pelvis and the prostate gland is thus examined bimanually. The degree of intravesical enlargement can be fairly accurately determined in the majority of cases if the patient is not too stout. The size of the gland is recorded—intravesical 0–4 plus, rectal 0–4 plus.

The Role of Radiography

A straight radiograph of the urinary tract should be taken in all cases. Prostatic, vesical, and renal calculi may be silent. Secondary malignant deposits in the pelvic bones and lumbar vertebrae may be seen.

Intravenous urograms should be taken in cases of Groups II and III, and at one of my clinics this is done as a routine in all cases. One can determine from the cystograms whether a crenellated bladder is present indicative of trabeculation of the bladder musculature, or a gross filling defect indicating a neoplasm. Diverticula may also be seen, and at times the degree of intravesical enlargement of the prostate observed. If the last radiograph is taken after the patient has passed urine the amount of residual urine can be assessed.

Intravenous pyelograms may also give one an indication of the function of each kidney, and any dilatation of the upper urinary tract will be observed. The presence of any filling defects of the pelvis or calices of either kidney may suggest a neoplasm. If there is failure in procuring perfect anatomical intravenous pyelograms in cases of Group III, then ascending pyelograms should be obtained.

Classification of Renal Function

The renal function may be *immediate*, taken on admission; *stabilized*, after vesical drainage for a period up to six weeks; *final*, after many months of suprapubic drainage. The kidney function in this series of cases has been determined by the blood-urea and urea-concentration tests. I have found these of great value, and as a result of observation of cases and their progress I have come to divide renal function into four classes. This classification has helped me to decide the type of operation and the most suitable time for its performance. The *blood urea* is taken before the urea-concentration test.

Urea-concentration Test.—In the first instance no fluids are allowed for 12 hours before starting the test at 5 a.m. If, however, this does not show a Class I kidney function it is repeated after 36 to 48 hours, fluids being taken freely until five hours before the test. Recent catheterization interferes with the urea-concentration test, and 12 hours should elapse before it is taken. 15 g. of urea in 100 c.cm. of water is given at the appointed time. The patient empties his bladder (if a catheter is not *in situ*), and the urine passed (or drained) at hourly intervals for the first three hours is collected and accurately measured in cubic centimetres.

Class I

Blood urea 45 (or under)	1.5 g. (or more) urea excreted in any 1 hour.
No fluids for 12 hours	Percentage of urea increases with each hour. 3.5 g. (or more) urea excreted in 3 hours.

Class II

Blood urea 45 (or under)	1.5 g. urea in any 1 hour.
No fluids for 5 hours	3.5 g. (or more) urea excreted in 3 hours.

Class III

Blood urea 45 (or under)	Urea-concentration test does not satisfy above particulars.

Class IV

Blood urea over 45

Choice of Method of Treatment

Until 1939 I treated practically all my cases by suprapubic prostatectomy. A few were treated by "resection" with McCarthy's resectoscope or Thompson's punch, and some by the perineal approach. The operation of choice was that of Harris, performed either in one or in two stages. In other cases a modified Freyer's operation was used, with destruction of any potential prostatic diaphragm. From 1939 onwards I employed Thompson's punch with increasing frequency, so that in this whole series 82.6% were operated upon by the perurethral route.

It is in my opinion a mistake to use one method to the exclusion of others. Each individual case should be judged on its own merits. Surgeons will vary in their views on choice of operation, depending to a great extent on their relative skill and experience of results with each, and also on whether they have the time, patience, inclination, and nursing staff to persevere with the difficult technique necessary for the perurethral method.

From the surgeon's point of view the perurethral operation is more arduous. It involves the use of a highly trained team, an electrical apparatus in perfect condition, and the performance of delicate manipulations at a distance over a long period in a relatively cramped position. There is no doubt that if a surgeon attempts perurethral prostatectomy without a full training in perurethral operative work and without the above advantages the results can reach only an indifferent standard and the method will fall into disrepute. From the patient's point of view the advantages are immense—the absence of an external wound and of suprapubic drainage, the general comfort, and a rapid convalescence.

There is no doubt in my mind that most cases are best treated by the perurethral route. The lay public have come to this conclusion also, and one has constantly to be on guard lest, against one's better judgment, the patient persuade one to perform a perurethral operation when the suprapubic method offers the best prospects.

There are many factors to be taken into account in the choice of operation. Some of them are as follows:

1. Size of Gland

Removal of the large gland by Thompson's punch is tedious, and if in order to avoid a further operation the surgeon persists longer than one hour, he may shock the patient considerably. The amount of tissue individual surgeons can remove at one sitting with safety varies very much. The maximum I have removed successfully with the present instrument at one sitting is 116 g., but in the hands of some surgeons this amount would appear to be by no means unusual. I feel, however, that multiple sittings are to be avoided if possible, and I prefer to remove these large glands of 80 g. or more by the suprapubic route provided there are no contraindications. The average prostate weighs 30 to 40 g., and thus the majority of cases are suitable for perurethral removal. The size of the gland can be determined before the operation by the method described, and it is thus possible from experience to decide whether the gland can be removed with Thompson's punch in one sitting with ease or with difficulty, or whether it is better removed by open operation.

2. Relation of Kidney Function to Type of Operation

Suprapubic Operation.—From the point of view of renal function it is safe to perform a one-stage prostatectomy on cases with a Class I kidney function. Practically all these cases have a small residual urine, but if it is over 2 to 3 oz. it is my custom to insert a catheter for a week before operation. The operation I perform is that of Harris. Cases in a lower class have urethral drainage in an attempt to improve their class, but if after seven to ten days Class I, or in certain cases Class II, function is not reached, a high suprapubic drainage and Steinach's operation are performed.

The renal function is reviewed again in three to four weeks' time. Many cases will by then have improved their class to I or II, and operation can be carried out. An intravenous drip is begun at the operation in the latter cases. Cases in Class III are a hazard for suprapubic operation, and difficulties are to be expected if any post-operative complications develop. If the patient is a good risk from other points of view the suprapubic method is justifiable, otherwise the gland is better removed by the perurethral operation in one or more sittings, depending on the size of the gland. An intravenous drip is necessary. Cases in Class IV are better operated upon by the perurethral route or discharged with a permanent suprapubic drainage until the final renal function is obtained after several months' drainage. The majority of these cases are suitable for operation by either route at the end of this time.

Perurethral Operation.—Cases with immediate Class I, II, or III kidney function are suitable for operation from the point of view of renal function. In cases of Class IV the bladder is drained by Foley's catheter and the kidney function allowed to improve as a result of the relief of back-pressure and the administration of copious fluids by mouth, and intravenously if necessary. Kidney function tests are repeated at weekly intervals if required, and one finds that the majority of cases rapidly improve their class. Thus a case may be admitted with a blood urea of 250, and after drainage for a few weeks the blood urea may have fallen to normal. Operation is performed as soon as Class II or III is reached. There are some cases, however, which fail to improve, and stay in Class IV after four to six weeks' drainage. They have reached their "stabilized function," and it is unlikely that any major improvement will occur for many months. These cases are often a difficult problem, and treatment will depend on the height of the blood urea and the general condition of the patient. If the blood urea is very high I prefer a suprapubic drainage for four to six months, the tests then being repeated. If the blood urea is only moderately raised I take the risk of operation, an intravenous drip being used after the operation and continued for two or three days or longer until 100 oz. of urine are drained in the 24 hours. Some surgeons operate upon cases with acute retention shortly after admission even though they have a raised blood urea of 100 or under. It is realized that once the obstruction has been relieved and the obstructing tissue removed, the kidney function will improve. In this series of cases this procedure has not been adopted, as the advantages have not seemed great enough to outweigh the disadvantages. It may be noted here that only veins in the upper limbs are used for intravenous drips. Patients are ambulatory at an early period and sepsis in wounds of the lower limb is liable to occur, with dangerous sequelae.

3. Cardiovascular Disease

Cases with cardiac decompensation usually improve rapidly once the chronic uraemia is relieved by urethral drainage. Many cases which would appear hopeless at first prove quite good risks after a few weeks. If fibrillation is present they are digitalized.

The cases which cause anxiety are those with gross hyperpiesia and those with a history of coronary thrombosis. These are preferably operated upon by the perurethral route. It is essential that no shock be permitted to occur during the operation and that the loss of blood be minimal. Once the blood pressure has been allowed to fall it may be difficult to get it back to normal limits, and, although the renal function may be excellent, secondary renal failure develops as a result of failure of the circulation. It is therefore my routine in these cases to have an intravenous drip started by my assistant immediately before or after the spinal anaesthetic has been given. Saline is used at first and plasma later if necessary, and the rate of drip is varied according to the blood pressure. The usual vasoconstrictor drugs are administered even though the patient has hyperpiesia. The operation time is made as short as possible, and several sittings may be necessary to remove a large gland.

The beneficial effect of prostatectomy upon the cardiovascular system is often most striking. Frequently patients previously suffering from angina of effort find that they are able to lead more active lives without this symptom occurring. In cases of hyperpiesia the blood pressure often falls, with resulting increase in the patient's comfort.

4. Coexisting Lesions in the Urinary Tract

(*a*) *Congenitally Narrow Urethra and Urethral Strictures.*—An obstructing prostate complicated by the above conditions should be removed by the suprapubic method. Perurethral surgery is apt to result in the stricture becoming more troublesome afterwards, and this will certainly be the case if the stricture is overstretched. This method should therefore be avoided if at all possible in these cases. If the suprapubic operation is very definitely contraindicated the punch is introduced through a small incision into the bulb of the urethra behind the stricture and a perineal perurethral prostatectomy carried out. In cases with meatal stenosis a plastic operation is performed first, and thus this condition, if existing alone, is no bar to the perurethral operation.

(*b*) *Sepsis.*—If no primary lesion is present in the upper urinary tract, infection usually responds rapidly to sulphonamides, alkalis, and urethral drainage. The case can then be operated upon by the perurethral route in the ordinary way. If for any reason a suprapubic operation is chosen it is performed in two stages.

(*c*) *Vesical Calculi and Non-malignant Papillomata.*—Unless of large size these are not of themselves important factors in determining the approach. If the perurethral operation is judged preferable from other criteria, the calculi are removed by crushing with a cystoscopic lithotrite, or the papillomata either destroyed by coagulation or excised with the punch or McCarthy's electrotome. If time permits the prostate is removed at the same sitting, otherwise a catheter is inserted and the gland removed a few days later. If papillomata have been present the irrigation fluid used is 1/5000 silver nitrate. I have had no cases of implantation growths in the prostatic cavity following this procedure. If the calculi or papillomata are of large size they are treated by suprapubic operation, and the prostate is removed at a later date by suprapubic or perurethral route, depending on the case.

(*d*) *Carcinoma of Bladder.*—The carcinoma is removed first and the prostate at a later date by the suprapubic route. The bladder capacity is small after the partial cystectomy, and operation by the perurethral route undesirable.

(*e*) *Vesical Diverticula.*—These are extirpated in the first instance, and if a prostatic bar is present this is destroyed at the same time by Irwin's clamp. Otherwise a prostatectomy is performed at a later date.

(*f*) *Prostatic Calculi.*—If these are of small size the gland is removed by the perurethral route, but if of large size by the suprapubic.

(*g*) *Lesions of the Upper Urinary Tract.*—Sepsis or urgent conditions in the upper urinary tract often necessitate a preliminary suprapubic drainage followed by treatment of the renal or ureteric lesion. The prostate is removed later, the type of operation being dependent on the factors previously mentioned.

5. Other Factors

There is no doubt that patients who are stout or suffer from bad chests are better operated upon by the perurethral route even though the gland is of large size. Gross varicose veins in the lower limb or a history of spontaneous thromboses are factors which may weight the scales in favour of perurethral prostatectomy. The incidence of thrombosis is very much less after this procedure.

Tables showing the results of treatment, the causes of death after prostatectomy, and reasons for not operating are given on the next page.

Commentary

All deaths are recorded, whether due directly or indirectly to the operation or from coexisting lesions in any other systems having no relation to the genito-urinary tract. All prostatectomies performed at my clinics are included in these results. In later years particularly, cases have been received from other clinics for perurethral prostatectomy as they were considered to be in too poor condition for open operation. The percentage of bad-risk cases is therefore higher than usual.

Statistics are apt to be misleading. One may, for example, deduce that Harris's one-stage prostatectomy and two-stage prostatectomy are the safest operations in view of the fact that no deaths occurred. In actual fact, only good-risk cases were operated upon by these methods, the gland being of large size.

The number of cases given only palliative treatment has been recorded. It includes those admitted to a voluntary hospital and also a municipal hospital, often suffering from advanced stages of various diseases.

In this series no case was rejected in which operation held out the slightest prospect of success. The cases operated upon include those with other diseases of the genito-urinary tract, such as carcinoma of the bladder, kidney, etc., and also diseases of other systems—e.g., carcinoma of the rectum.

Summary

The object of this paper is to show the good results of radical treatment for prostatic obstruction and to urge that these cases be

Table I.—*Results of Treatment of 875 Patients admitted with Prostatic Symptoms*

	No. of Patients	Percentage of Total	Admitted with Acute Retention	Mortality Rate
Perurethral prostatectomy ..	621	70·97%	228 (35·11%)	3·7% (23)
Suprapubic prostatectomy ..	131	14·97%	67 (51·15%)	2·29% (3)
Modified Freyer's (2-stage)	49		27	—
Harris's (*a*) 1-stage ..	21		5	—
(*b*) 2-stage ..	61		35	3
Permanent suprapubic cystostomy	94	10·74%	68 (72·34%)	11·7% (11)
No operation	29	3·32%	Transferred to a chronic ward	

Mortality from all causes following prostatectomy is 3·4% in a consecutive series of 752 cases. Mortality of the last 439 perurethral prostatectomies in this series = 2·51%. Of all prostatectomies 82·6% were performed perurethrally, 17·4% by various suprapubic methods. The oldest patient subjected to perurethral operation was aged 90.

Table II

Reasons for Leaving Permanent Suprapubic Cystostomies	No. of Cases	Reasons for Not Operating at All	No. of Cases*
Bad renal function (persistent high blood urea)	31	Mentally violent	8
Cardiac disease	17	Cardiac disease	6
Poor general condition	12	Poor general condition ..	5
Intercurrent death	11	Intercurrent death	5
Refused further operation ..	7	Uraemia	2
Other severe disease or senility..	6	Other severe disease or senility	2
No records	10	Refused operation	1
Totals	94		29

*All these were cases from the municipal hospital.

Table III.—*Cause of Death after Prostatectomy*

Cardiac failure, coronary thrombosis, and pulmonary embolism	11
Uraemia	4

sent early to the surgeon. A clinical method of diagnosis, to prevent cases being missed, is described in detail. The indication for various types of operation is discussed. The perurethral operation is considered the method of choice. The paper is based upon a series of 875 consecutive cases, of which 752 were submitted to radical operation, with a mortality of 3.4%, 82.6% being treated by the perurethral method.

I wish to express my thanks to the sisters, nurses, and house-surgeons who have worked with me and without whose care and attention these results could not have been obtained. I also wish to thank my clinical and private assistant, Mr. Hadda, for the help he has given me and for compiling the statistics.

PARADOXICAL EMBOLISM

WITH REPORT OF A CASE DUE TO A VENTRICULAR SEPTUM DEFECT

BY

C. ALLAN BIRCH, M.D., F.R.C.P.
Chase Farm Hospital, Enfield

Various mechanisms have been advanced to explain how an embolus may avoid the lungs and pass from the systemic veins or right heart to the systemic arteries. The earliest explanation of the apparent contradiction to the normal path of emboli was that small ones could occasionally traverse the lung capillaries. This seems very unlikely. Experimental work suggests that even air cannot pass through the pulmonary circulation in harmful quantities. A patent foramen ovale has been present in fatal cases of paradoxical air embolism (Thomassen, 1938) and may have been present in non-fatal cases.

Since Cohnheim (1877) first traced the path of an embolus through an opening in the interauricular septum many such cases have been reported. An anatomically open interauricular septum may be functionally closed because the higher pressure in the left auricle ensures that it is closed by a valve on the left auricular side. Beattie (1925) suggested that this relation might be repressed by the lodging of a pulmonary embolus in the pulmonary artery which raises the pressure in the right auricle and at the same time lowers it in the left auricle because of diminished return from the lungs. A subsequent embolus arriving in the right auricle would be swept through to the left auricle and thence to the aorta. Thompson and Evans (1930) believed that at least one-third of the pulmonary arterial circulation had to be depleted before the right auricular pressure became greater than the left auricular pressure. That this mechanism is a possible one is suggested by the fact that in Wittig's (1927) series 50% of cases of paradoxical emboli were associated with antecedent pulmonary embolism. Some other explanation is necessary for those cases in which pulmonary embolism is absent or minimal. The simplest is that it is entirely fortuitous; a widely patent foramen ovale allows the embolus to pass without the help of pressure changes. Taylor (1934) suggested that shock from passage of a small embolus to the lung may bring about pressure changes which facilitate passage of a subsequent embolus through a patent foramen ovale. There is no experimental confirmation of this. Where the foramen is guarded by a valve Porter (1941) suggested that the embolus coils up over the tricuspid valve and obstructs it momentarily, so that the pressure rises in the right auricle and opens the foramen, allowing the embolus to pass through.

Paradoxical embolism may occur through a patent ventricular septum. If in addition the aorta arises from the right ventricle an easy route is provided for an embolus from a systemic vein to reach the aorta. Two such cases were described by Abbott and Beattie (1923) in which paradoxical embolism of the brain had arisen from septic foci in the arm and abdomen respectively. Only six examples of paradoxical embolism for which a ventricular septum defect was responsible have been reported. Louis (1826), in an article on communications between the right and left sides of the heart, described the case of a man aged 25 years in whom two areas of cerebral softening were found. The ventricular septum was defective at the base. No other cardiac anomaly was present. His description seems to indicate that the patient also had extensive pulmonary tuberculosis, and there is no clear evidence that the brain lesions were not tuberculomata. He did not draw any conclusions from these findings, but embolism was unknown in his day, being elucidated by Virchow only in 1845. Ballet (1880) collected a series of seven cases of congenital heart disease with cerebral abscess. In two of them a ventricular septum defect was the only anomaly. One was Louis's case and the other his own. This was a male of 15 years who died of a frontal abscess. The heart showed a ventricular septum defect with a malposed septum and an aplastic right ventricle. He assumed but did not explain the connexion between the septum defect and the cerebral abscess. Although the state of the peripheral veins is not given, the nasal fossae and cranial bones were normal, and paradoxical embolism seems to have been the probable cause. Stone (1881) reported the case of a female aged 19 years with a large ventricular septum defect and acute endocarditis of the stenosed conus of the right ventricle. She died of purulent meningitis and a cerebral abscess. No comment on the origin of the abscess was made. Hanna (1941), reviewing the 35 cases of paradoxical embolism reported up to 1941, found three (those of Louis, Ballet, and Stone) in which a ventricular septum defect was responsible, and added three of his own. In all six cases embolism was cerebral, and in none was the source of the embolus found.

In the case here reported the embolus consisted of vegetations from the pulmonary valve. It is suggested that they were large enough to lie over the opening in the septum and, when they broke off, to pass through it into the left ventricle. Pulmonary emboli were absent.

Case Report

A boy aged 11 had been blue and dyspnoeic on exertion since birth, and at the age of 6 was found to have congenital heart disease. At the age of 10 he had tonsillitis and cervical adenitis. A moderate amount of haematuria at the time was attributed to the nine days' sulphonamide treatment before admission to hospital, for no evidence of bacterial endocarditis was found. There was a very loud apical systolic bruit, and a basal to-and-fro bruit at the pulmonary area. He was readmitted at the age of 11 with pyrexia, sore throat, and pain in the right leg attributed to acute rheumatism. His temperature was 103° F. It was found that the pain was due to arterial occlusion, and as similar signs were appearing in the left leg a diagnosis of embolism of both common iliac arteries from bacterial endocarditis was made. Haematuria was present, but urinary output was good. *Streptococcus viridans* grew on blood culture. He died four days later. At the necropsy a large embolus straddled the aortic bifurcation and completely occluded the right and a portion of the left common iliac artery. Recent infarcts were present in the left kidney and spleen. The mitral and aortic valves were normal. A large defect was present in the ventricular septum, but the auricular septum was normal. The cusps of the pulmonary valve could not be identified, and were replaced by a mass of friable vegetations. No infarcts were found in the lung.

ACTINOMYCOSIS SUCCESSFULLY TREATED WITH PENICILLIN

REPORT OF TWO CASES

BY

A. J. C. HAMILTON, F.R.C.S.

AND

H. J. R. KIRKPATRICK, M.B., Ch.B., D.P.H.

(*Royal Northern Infirmary, Inverness*)

Actinomycosis is not a common condition, and opportunities for observing the effects of its treatment with penicillin are consequently infrequent. Roberts *et al.* (1945) record two cases of thoracic actinomycosis. One of these patients died from *Ps. pyocyanea* pyaemia after a week's treatment with penicillin; the other relapsed after one course of treatment (1,800,000 units administered systemically in 15 days), but recovered after a further course of treatment (200,000 units daily for 28 days). Hendrickson and Lehman (1945) record two cases of cervico-facial actinomycosis successfully treated with penicillin. In one case 2,000,000 units of the drug were administered in 16 days; in the other 1,500,000 units in 15 days. In a case treated by Macnab (1945) (daily intramuscular injections of 100,000 units for 10 days) penicillin had no apparent effect on the course of the disease.

We record below two cases of cervico-facial actinomycosis in which treatment with penicillin resulted in clinical cure. In one of these (Case 2) the history and physical signs pointed to the development of the lesion in the tonsillar lymph gland. There was no apparent actinomycotic lesion of the mouth or throat, but presumably lymphatic infection occurred through the tonsillar region. The occurrence of actinomycosis in lymph glands has been denied by some observers, and recently by Macnab (1945), but has been accepted by Cope (1938), who depicts actinomycotic lesions in photomicrographs of lymph glands.

Case Histories

Case 1.—A linotype operator aged 35 was admitted to hospital on May 15, 1945, with a large, brawny, smooth, painless, semi-fluctuant swelling situated over the inferior ramus of the left mandible. The swelling was ill defined, and extended upwards over the anterior border of the masseter muscle and downwards for a short distance into the submaxillary triangle. One enlarged lymph gland was felt at the anterior border of the sternomastoid. There was marked caries of the teeth. The lesion had apparently started 14 days before admission as a "gumboil" over the left lower jaw. Three teeth had been extracted on May 12. The lesion was incised and pus evacuated on the day of admission.

Case 2.—A railway porter aged 15 attended as an out-patient on May 31, 1945, with an enlarged right tonsillar gland, showing periadenitis and tenderness. He gave a history of a swelling in the right side of his neck a year before, which had soon disappeared. Nine weeks before admission he developed a sore throat, and the swelling in the neck reappeared and showed no tendency to diminish in size. Both tonsils were grossly enlarged and almost touching; the teeth were healthy, although some had been extracted a year and a half previously. He was referred to Dr. Seex, who removed his tonsils by dissection on June 4. He was readmitted to hospital on June 14 with a brawny swelling of the neck, the inflammation now being definitely extracapsular. This was treated with ichthyol-and-glycerin foments, and was incised on June 22. Thick greenish pus was evacuated, and a rubber dam drain was left in the large abscess cavity.

Bacteriology.—The pus from both cases contained streptothrix filaments. These organisms failed to grow under aerobic conditions in primary cultures and in subcultures. In glucose-agar shake-cultures there was no growth in the upper centimetre of the medium, and growth was maximal in a zone situated one centimetre below the surface of the medium. Growth occurred under anaerobic conditions but less readily than under micro-aerophilic conditions. Microscopical examination of the pus from Case 1 showed scanty Gram-positive cocci as well as streptothrix filaments, but the cocci failed to grow in aerobic and anaerobic cultures, and were presumably non-viable. Only streptothrix filaments were noted in the pus from Case 2.

Dosage of Penicillin and Method of Administration.—In both cases penicillin was administered systemically by intramuscular injection. During the first half of the course of treatment the dosage was 33,000 units every three hours; thereafter the dosage was reduced to 25,000 units every three hours. There was a gradual diminution in the size of the lesion, and treatment was continued until the discharge had ceased and the lesions had markedly diminished in size. Case 1 received in all 5,800,000 units of penicillin, and Case 2 5,200,000 units.

The patients were re-examined a month after discharge from hospital. In both there was slight thickening of the tissues at the site of the lesion but no evidence of an active inflammatory process.

Discussion

Different strains of *Actinomyces bovis* vary in their susceptibility to penicillin. Of five strains examined by Garrod (1944) and compared with the Oxford H strain of *Staphylococcus aureus*, two strains showed approximately the same degree of sensitivity as the standard staphylococcus; a third strain was eight times as resistant; a fourth strain four times as resistant; and a fifth strain grew sparsely and atypically in 16 times the concentration of penicillin tolerated by the staphylococcus. The patient from whom this fifth strain was isolated was not treated with penicillin.

Fibrous-tissue formation is an outstanding characteristic of the pathology of actinomycosis—its amount and maturity varying with such factors as the age and site of the lesion, the resistance of the patient's tissues, and the virulence of the infecting organism. The amount of fibrous and granulation tissue, and its age, affect the vascularity of the lesion and the flow of blood through it, and consequently the permeation of the lesion by penicillin in the blood and the concentration of the drug attained in different parts of the lesion. Further, actinomyces may show a considerable degree of latency, and relapse may occur a long time after apparent cure (Cope, 1938).

Local treatment could not be applied in the two cases here described, and the relatively high dosage of penicillin administered systemically and the duration of the treatment were based on the response to treatment and on the above considerations, which seem to indicate the need for high dosage and a prolonged course to ensure success in the treatment of this disease with penicillin.

The results obtained strikingly demonstrated the curative effect of penicillin, but more prolonged observation of the patients will be required to ensure that no viable actinomyces capable of proliferation remain embedded in the tissues.

The first two of the lecture-demonstrations arranged by the British Medical Students' Association for its members in the London Region have now taken place. Mr. Claud Mullins opened the series with a talk on "Medicine and the Magistrates' Courts," and many students have since visited his court to see a demonstration of some of the points he made. Prof. E. Hindle gave an address on "The Prosectorium of the Zoo," and later conducted a party round the Zoological Gardens and the post-mortem department to demonstrate the investigations made into the physiology, anatomy, and pathology encountered among the animals. Details of future talks and visits (open to members of the Association only) may be obtained from the B.M.S.A. secretary at B.M.A. House, Tavistock Square, W.C.1.

Medical Memoranda

Torsion of Omentum

The following case is felt to be worth recording because of the rarity of the condition.

HISTORY OF CASE

The patient, a man aged 23, was admitted on April 7, 1943, as a case of acute abdomen. Four days previously he felt acute pain in the upper part of the abdomen, which became more severe round the umbilicus, later localizing itself in the right iliac fossa; there was no vomiting and the bowels had moved well before the onset of pain. Three months earlier he had had similar pain starting round the umbilicus, accompanied by severe vomiting, and was treated in a general hospital. The attack lasted over 10 days. He does not remember whether the pain was localized in the right iliac fossa, and if so, whether there was any tenderness or rigidity.

On admission the patient looked very ill; he was emaciated and exhausted, with cheeks drawn in. In spite of his condition he walked up to the hospital M.I. room, and from there to my consulting-room. Temperature 99.6°, pulse 84, and respirations 19; general condition poor. The scaphoid was more or less fixed, with very limited movements on respiration; a lump could be seen in the right iliac fossa; superficial reflexes were dull in the upper part, absent in the lower. A definite mass was felt in the abdomen in the region of the caecum; the abdominal wall was rigid, hyperaesthetic, and tender, with no fluctuation—suggestive of local peritonitis. Rectal examination revealed a hard tender mass. The tongue was dry and furred; lungs and heart—nothing abnormal. The provisional diagnosis was acute appendicitis. Blood examination showed: R.B.C., 3,750,000; W.B.C., 9,800 (polymorphs 77%). Urine examination revealed nothing abnormal.

Treatment.—After premedication with morphine and atropine, spinal percaine analgesia was given. As the patient lay flat on the table a definite lump (mound) could be seen on the right side in an otherwise scaphoid abdomen. The abdomen was opened by McBurney's incision in the right iliac fossa; the peritoneum was incised very cautiously, as free pus was expected, but there was none. Instead of pus a large mass of dark cherry-red colour was seen, with a finger-like process closely adherent to it, giving the appearance of a "gangrenous appendix with a mass." When the finger was put in, the whole mass could be moved about freely, and thus was brought out; it was the terminal portion of the omentum, which had twisted on itself, its size being that of a tennis ball. Luckily it was not adherent to any of the viscera. Between clamps the mass was removed and the proximal end was firmly ligatured. The caecum was then examined and found to be normal and healthy; so was the appendix, which was in the retrocaecal position. The appendix was, however, removed as a safeguard against any future attacks. After thoroughly mopping the abdomen the cavity was closed. Recovery was uninterrupted and convalescence very rapid. On April 16 (ninth day) the stitches were removed and the wound had healed by first intention.

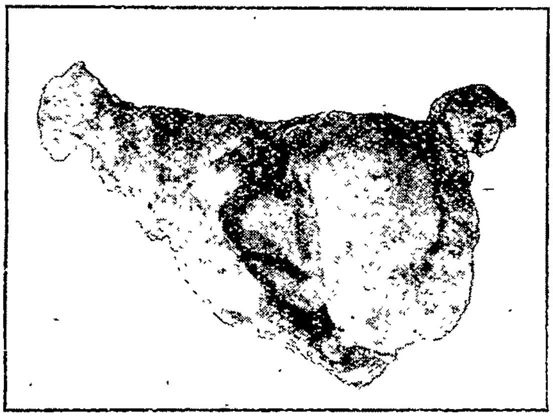

Photo of specimen, showing the twist, the finger-like process, and the mass of omentum. (A piece was removed from the middle for histological examination.)

The specimen was sent to the pathological laboratory, where it was examined by the Consultant Surgeon and the Assistant Director of Pathology, Paiforce, macroscopically and microscopically. The diagnosis was confirmed as torsion of the omentum.

COMMENT

The condition has not been, and cannot be, diagnosed before laparotomy. Nearly always the pre-operative diagnosis is acute appendicitis. The caecum and appendix, though in the vicinity, are not affected at all. Treatment is simple.

None of the surgeons to whom I talked about this case could recollect having ever come across a similar condition in their own extensive experience, though most had seen bottled specimens in the museum. I can therefore at least claim to have a first-hand knowledge of the condition, as seen in the natural state.

What the actual cause is cannot be definitely stated. It may be some sort of exertion—the patient gave a vague history of having done some P.T. on the morning of the attack—or thrombosis of the vessels (in this case the vessels were thrombosed). But whether the thrombosis preceded the twist or followed it is not known. As I am out in the desert and have no access to any literature, I am afraid it is not possible for me to say anything more on this interesting subject.

M. N. KHANNA, F.R.C.S., F.R.C.S.Ed.,
Major, I.M.S.

Treatment and End-results of Acute Appendicitis

Opinion is almost unanimous that for acute appendicitis while the disease is still limited to the appendix the treatment of choice is appendicectomy without drainage of the abdomen. When peritonitis is established surgeons have been sharply divided in opinion since Ochsner (1906) and Sherren (1905, 1925) advocated conservative measures in late cases. The availability of blood plasma and the sulphonamide drugs has done so much to improve the end-results of operation that it is difficult, with the sole exception of certain localized abscesses, to justify conservative treatment. Since it is among cases of general peritonitis that the mortality occurs, detailed considerations will be limited to that group.

Sulphonamide Therapy.—The sulphonamides are unnecessary except in cases of general peritonitis. While plasma transfusion is in progress, a pre-operative injection of 2 g. of soluseptasine is given intramuscularly. At operation 15 g. of sulphanilamide powder is inserted intraperitoneally, followed by 1 g. intramuscularly at four-hourly intervals and a further 1 g. by mouth if necessary. I prefer sulphanilamide powder intraperitoneally because of its rapid absorption. Most help appears to be required in the first two days after operation; the peritoneum then seems to be able to look after itself. The general condition of the patient and the passage of flatus appear to be safer guides in gauging the dosage and duration of the course than the temperature chart. There have been no toxic manifestations, and operation on two cases a year later leaves one with the impression that adhesion formation may be diminished after its use.

Drainage.—Extensive drainage has great advantages in severe cases. A split rubber tube (split to pubis) from the pelvic floor is essential in almost all cases. In addition, a strip of corrugated rubber is brought out through the wound from the appendicular bed; and in a desperate case a tube in the subhepatic pouch has the advantage of draining the abdomen before the patient has recovered sufficiently to assume the Fowler position. It may be of value in avoiding a subphrenic abscess.

After-treatment.—The most important and most neglected after-treatment in all cases is the passage of a flatus tube every three hours. Should a severe ileus develop, aspiration of the stomach, eight-hourly morphine injections, and plasma transfusion give results far superior to those of any form of "stimulation" therapy and render doubtful procedures like ileostomy unnecessary. Convalescence is often slow and anxious: many cases required five weeks in bed.

End-results.—In a series of 200 consecutive personal cases of acute appendicitis there was one death. That was due to peritonitis. No cases have been rejected on account of severity of disease or delay in diagnosis. The results are summarized in Tables I and II.

TABLE I

Total cases of acute appendicitis	200
Acute appendicitis without peritonitis	164
Localized abscess (7 drained—2 pelvic in site)	15
General peritonitis (one death)	21

TABLE II.—*Duration of Disease in Peritonitis*

Duration	Cases
1–12 hours	1
13–24 „	0
25–48 „	2
49–72 „	10
4–5 days	4 (1 death; boy aged 16)
5–6 „	2
7–8 „	2

Reviews

FEMALE UROLOGY

Gynecological and Obstetrical Urology. By Houston S. Everett, M.D. (Pp. 517; illustrated. $6.00 or 33s.) Baltimore: The Williams and Wilkins Company; London: Baillière, Tindall and Cox. 1944.

This is a "different" book: different because it comes from a medical school that is itself in some ways "different."

Gynaecology in Johns Hopkins Hospital is a subdivision of surgery; it has never united with obstetrics to form a specialty of its own. One consequence of this has been that workers in the department of gynaecology undertake investigations and treatments that would usually be regarded as outside the scope of the specialty. This trend is seen in the development of the now famous Female Urological Clinic. Howard Kelly, founder of the Gynaecological Department, made female urology a special interest. His work received world-wide recognition. With Burnam he wrote a treatise on this subject which is still one of the great books of reference. Kelly's assistant, G. L. Hunner, later assumed control of the urological clinic, and over a long period of years maintained and added to its renown. Recently the control has again changed hands; and the present director, H. S. Everett—for many years Hunner's assistant—has now undertaken the considerable task of writing a new comprehensive textbook on female urology which includes a full description of the methods that have come to be particularly associated with his hospital. Because he has been trained in gynaecology, and now works in association with other gynaecologists, he approaches urological problems from an unusual (but natural) standpoint.

The writing is clear in style (if at times a trifle verbose), the illustrations are numerous and of excellent quality; printing errors and wrong positioning of illustrations (so common in first editions) are almost absent. The bibliography is extensive, though comparatively sparse in regard to European literature. The curious reader naturally turns to those chapters dealing with the special methods developed by Kelly and Hunner, and he is fully rewarded. An excellent description is given of the Kelly direct (air) method of cystoscopy and ureteral catheterization. The ureteral "stricture" of Hunner, and its special treatment with wax-moulded bougies, are fully described. The pathology and treatment of interstitial cystitis (the "elusive" ulcer of Hunner) are convincingly presented.

This book merits high praise. Where the teaching is orthodox the descriptions given are excellent; where unorthodox, the disputed opinions are presented with a care and restraint that claim from the reader serious thought and consideration. The publication will make a strong appeal to both urologists and gynaecologists. It bridges the gap that exists between the two specialties.

X-RAY EXAMINATION OF THE UPPER ALIMENTARY TRACT

X-ray Examination of the Stomach. A Description of the Roentgenologic Anatomy, Physiology, and Pathology of the Oesophagus, Stomach, and Duodenum. By Frederic E. Templeton, M.D. (Pp. 516; illustrated. £3.) Illinois: University of Chicago Press; London: Cambridge University Press.

X-ray Examination of the Stomach, by Frederic E. Templeton, has a wider range than its main title indicates, for it includes the pharynx, oesophagus, duodenum, and diaphragm. It is a book of some 500 pages and nearly 300 illustrations. The reviewer would like to make it clear that, whatever criticisms follow, this is a book of first importance and it contains a wealth of information on the subject.

After describing his own apparatus—a fairly standard American tilting-table set—the author gives the details of his technique of investigation. This is an excellent survey of a modern technique, but a note of unreality is introduced by the suggestion that excess of resting juice in the stomach should be removed, as a routine measure, by aspiration and lavage. Does Dr. Templeton really achieve this in his own practice? If so, the American patient must be more long-suffering than the British. The chapter on the anatomy and physiology of the oesophagus is exceptionally good and gives a full account of the mechanism of swallowing. It includes a description of the author's method of demonstrating the pharynx filled with barium. The difficult and still unclarified subject of gastritis is discussed in great detail, and here the author shows a commendable reserve in his conclusions. In dealing with peptic ulcer the appearances of the ulcer crater are considered with profusion of detail, which makes certain omissions the more astonishing. Pyloric obstruction is not described, nor is organic hour-glass contracture. Arterio-mesenteric duodenal ileus finds no place in the index, or in the text. This patchiness is evident later on in the book, when the chapter on the stomach after operation proves to be full and informative, while that on the diaphragm is very meagre. Indeed, the description of Petit's eventration would, if given by a D.M.R. candidate, seriously endanger his pass mark.

In a book that contains much that is good it is a pity that one should, in the search for the good, have to wade through such an irritating *non sequitur* as the following (p. 285): "There can be no doubt that the crater is the most important single factor in the diagnosis, for the ulcer is the crater. It can, therefore, be considered the primary anatomic change." Again, in discussing a superficial peptic ulcer the author says, of "faint persistent rounded collections of barium," seen on compression of the bulb, that "the rapid disappearance under medical ulcer management left grave doubt as to whether an ulcer actually existed. That an ulcer did exist is suggested by the quick response of the clinical symptoms to the treatment." Throughout the book a praiseworthy accumulation of accurately noted facts is interlarded with ambiguous redundancies like the above; but if the reader is prepared to work hard and ignore the irrelevances he will be well rewarded, for there is much meat in the volume. One last word: the illustrations are well chosen and beautifully produced.

LEGAL MEDICINE

Medical Jurisprudence and Toxicology. By John Glaister, D.Sc., M.D., F.R.S.Ed. Eighth edition. (Pp. 691; 222 illustrations, 89 in colour. 30s.) Edinburgh: E. and S. Livingstone. 1945.

This eighth edition of Glaister should have appeared even earlier, but unfortunately much of the work was destroyed by fire and had to be repeated. Since the seventh edition was published in 1942 many changes in the book have been made. A good deal of new matter has been added, particularly concerning the procedure of courts of England and Scotland, the law of cremation, asphyxia, the identification of firearms and projectiles, head injury and insensibility. The section on the presumption of survivorship has been taken as far as the Court of Appeal's decision in the Grosvenor case; but the exhaustive judgments of the House of Lords, which reversed the decision by a majority, were delivered after the book was in print. Prof. Glaister adds another interesting case concerning two brothers who were found dead together, one having gassed himself suicidally, and the other having died by accident through the escape of the gas.

The section on divorce for insanity has been brought up to date by consideration of the Safford case, with its decision that absence on licence from a mental hospital does not interrupt the patient's detention. New also in this edition are remarks on the proposed social insurance system, the condition known as "immersion foot" (which has somehow escaped the compiler of the index); the effect of crush injury on the function of the kidneys; the Rh factor in the blood which underlies erythroblastosis foetalis; agglutinogens in saliva; and the management of the property of persons of unsound mind. Some of the new poisons developed during the war, and the sulphonamides, have found their way into the toxicological section. The section on alcohol has been amplified by a table showing the relation between the consumption of whisky, wine, and beer and the alcohol content of the blood; also a description of the method of Kozelka and Hine for estimating blood alcohol.

The eighth edition contains 90 more illustrations than the last. Of the total, 120 pictures are new and 89 are in natural colour—an important new departure and by no means an easy task in these days. From one or two hints in the preface it is clear that the appearance of this new edition at all represents a triumph over a series of extremely difficult circumstances. That its excellence should surpass that of the previous edition is an achievement of the apparently impossible. Prof. Glaister, with one or two other noted contemporaries, deserves much credit for having produced, in a country conspicuous for its neglect of medical jurisprudence, a standard textbook that will rank with any in the world.

Notes on Books

Dr. RICHARD EAGER, consulting psychiatrist to the Royal Devon and Exeter Hospital and late medical superintendent of the Devon Mental Hospital at Exminster, has written a small historical work *The Treatment of Mental Disorders (Ancient and Modern)* to commemorate the centenary of the building of the Devon County Lunatic Asylum in 1845. It is published at Exeter by W. V. Cole and Sons and distributed in London by H. K. Lewis and Co., price 7s. 6d. Friends of the institution with which Dr. Eager was so long identified will be glad to have a copy of this book, and it should find many other readers.

The third edition of W. E. BRAY's *Synopsis of Clinical Laboratory Methods* (Henry Kimpton; 25s.), in spite of additions necessitated by the advances of the past six years, remains of pocket size, owing to the use of small type and the terse presentation conforming to the first word of its title. The author is professor of clinical pathology in the University of Virginia, and the text follows standard American practice: some doubtless useful tests are described with which we are not familiar, and on the other hand there is no mention of tellurite media for cultivating diphtheria bacilli. All branches of clinical pathology are dealt with, and the instructions given, though brief, should enable the user to set about examinations with which he is unfamiliar.

The second edition of *Handbook of Diagnosis and Treatment of Venereal Diseases*, by Dr. A. E. W. MCLACHLAN (E. and S. Livingstone; 15s.), contains 6 pages more than the first; the main addition is a more up-to-date account of the treatment of early syphilis, including the "20-day" and "7-week" methods and the use of penicillin. In addition, neo-halarsine is mentioned, and the sections on the causes of false positive serum reactions and on jaundice have been brought up to date. Many of the errors occurring in the first edition have been corrected, but "symtomatic" (p. 81) remains, and instances of plural nouns with singular verbs, and vice versa, still occur. The purist reader will carp at "the serology is positive" and "serological changes in the C.S.F.," while nowadays few syphilologists put much faith in the "provocative" W.R. or the Kahn verification test. The fact that a second edition has been produced so soon after the first is evidence that this excellent little book is being read widely.

Thirty-seven years ago the first edition appeared of a book, *Hey Groves' Synopsis of Surgery*, which has proved its value to the surgical student through its eleven subsequent editions. Now Hey Groves is dead, and the editorship of his *Synopsis of Surgery* passes to C. P. G. Wakeley, though the revision of the twelfth edition had been almost completed by the original author. Fittingly his portrait appears as a frontispiece to this edition. The general character of this book is so well known as to need no description; to bring the material up to date paragraphs have been added concerning the use of penicillin and the sulphonamides, and some notes on radium therapy. Despite these commendable additions to keep the book abreast of new developments we cannot help feeling that a book first written so long ago, and so excellent for its purpose at that time, now needs more than an occasional patching up as new editions are prepared. The synopsis really requires, to use a much-abused word, complete rehabilitation. It is published at 25s. by John Wright and Sons, of Bristol.

The National Association for the Prevention of Tuberculosis (Tavistock House North, Tavistock Square, W.C.1) has published at 5s., under the title *Pathways in Aftercare*, a report of the discussion on after-care and re-ablement for tuberculous patients, held in London last July. The conference was attended by many industrial managers, representatives of local authorities, specialist doctors, and welfare workers. The booklet gives a verbatim account of the speeches just as they were delivered, and it is hoped that their appearance in print will promote a free circulation of ideas on one of the gravest health problems of to-day.

The *Irish Medical Directory and Hospital Year Book, 1945*, is published in Dublin by the Parkside Press Ltd. (10s. 6d.). This, the eighth edition, has been produced in royal octavo size, a change which makes it easier to handle and more convenient for bookshelves. The need to reset the type from end to end has given an opportunity to carry out extensive revisions. The volume opens with a few pages of general information. Then follow eight special articles, each by an authority on his or her subject; these, with one exception, are clinical. Next comes the Medical Directory for Eire, well set out alphabetically in double columns, with other classified particulars useful to medical practitioners and officials. The Hospital Year Book and Index to Hospitals completes the volume, which runs to 300 pages of text and advertisements. Altogether a very handy work of reference.

We have received from the American Library of the U.S. Office of War Information (1, Grosvenor Square, London, W.) a reprint of the symposium on fractures and dislocations originally published in the *Surgical Clinics of North America* for February, 1945 (W. B. Saunders Company, Philadelphia and London). This symposium, to which fourteen surgeons contributed, was held at Chicago under the direction of Dr. Fremont A. Chandler.

Preparations and Appliances

HEATED CARRIER FOR TRANSPORTING PREMATURE BABIES

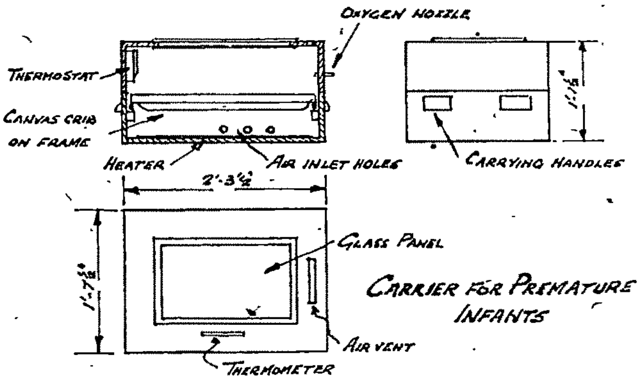
Dr. J. N. O'REILLY, M.R.C.P., writes from St. Helier County Hospital, Wrythe Lane, Carshalton, Surrey:

The difficulty of maintaining the body heat in a newborn premature baby is well known, and many devices have been developed to cope with the problem in hospital. Chilling is one of the principal causes of death of premature babies born on the district and subsequently transported to hospital for treatment. Various forms of heated carriers have been devised, principally in America, but most of them suffer from being over-elaborate and containing materials unobtainable in wartime.

A description is given here of a heated carrying-box designed and made by the hospital engineer, Mr. L. Selleck. The box is kept in a warm room in the maternity department, and when a request for the admission of a premature baby is received the interior is heated by means of hot-water bottles. The box is then placed in the ambulance and the heat is maintained by plugging into the ambulance batteries. On arrival at the patient's house the box is carried into the house and the baby is placed inside. In this way the infant is transported in a draught-free heated atmosphere of uniform temperature and with the minimum of handling.

Since the use of this box the condition of the babies on arrival in hospital has been much better than previously.

The carrier is a box made in halves and hinged together, the top half being fitted with an observation window. A changeable canvas crib is mounted on a frame supported on springs at the top of the lower portion of the carrier. Ventilation is provided by means of a number of holes in the sides under the crib, and by a slot in the cover. The air is warmed by means of an electric resistance heater and automatically maintained at a temperature of approximately 80° F. by the inclusion of a thermostat, the increased temperature of the air causing a continual air charge by convection. In addition to the thermostat a thermometer is embedded in the cover beside the observation window, with the bulb inside to give a visual indication of the temperature. Oxygen can be administered through a nozzle inserted at the end of the carrier, the inner end of the nozzle being splayed to give adequate distribution. The electric heater is of ample surface and so designed that the temperature of the element does not exceed 100° F. when operating on the 6–12-volt circuit provided by the ambulance battery.



The carrier is being further developed to design an incubator for premature infants. In this instance autocontrolled humidity will be available in addition, and facilities incorporated for easy manipulation. The heater will then also be designed for mains voltage.

WILL THERE BE AN INFLUENZA EPIDEMIC?

The possible intensity of the usual winter rises in the incidence of infectious diseases attracts attention in the autumn. This year interest is naturally focused on influenza, and there seems to be a general fear that the expected seasonal rise may be of epidemic proportions. Knowledge of the periodicity of influenza is imperfect; it is, of necessity, based on mortality, as the incidence of the disease is not recorded. It is known that the mortality varies much in different outbreaks, and the apparent irregularity in the spacing of large epidemics may be due in some measure to the use of deaths as the criterion of the size of the outbreak; it is possible that in some years influenza may be very prevalent but the case fatality very low. During the inter-war period a heavy mortality from influenza occurred at intervals of two to four years, and on this criterion the years when the disease reached epidemic proportions were 1922, 1924, 1927, 1929, 1933, and 1937. The deaths recorded in England and Wales in these years varied from 17,122 in 1937 to 29,084 in 1929, while in the intervening non-epidemic years the annual deaths ranged from 5,019 to 13,211.

The unusually long interval since the appearance of a large epidemic does increase the probability that an outbreak of more than average severity is due. The knowledge acquired in the pandemic of 1918, which caused 112,229 deaths in 1918 and 44,801 deaths in 1919, adds still further to the necessity for taking precautions against a major outbreak. Among the various contributory factors held responsible for the large mortality in the winter of 1918, the unusual time of the original outbreak and the great amount of overcrowding, combined with the fuel shortage, were generally agreed to be of prime importance. The first of these factors must remain an unknown quantity until an outbreak occurs, but the other two, if they do exert pressure on the course of epidemics, are now potential dangers. Overcrowding is certainly much worse than it was at the end of the war of 1914–18, and although it is not easy to assess the relative position of the fuel shortage in the two wars it is certain that the present outlook—and the immediate future—is a bit bleak. One must, too, take into account the belief held by some that the long period of minimum rations has already impaired the nation's power of resistance to infection.

If the trend of influenza could be predicted with any accuracy from these factors alone, then the outlook would be unpromising. But influenza does not run true to form —or, rather, we do not yet know just what the form is. Despite the spate of papers turned out by the press after the last pandemic, and the vast amount of work done before and since, our knowledge of the mechanics of the disease is more vague than exact. The shape of the epidemic curve in one area is very similar year by year, although the start of the outbreak may differ in time by some weeks. A comparison of big outbreaks shows that the disease runs a similar course in various parts of the world. The size of the seasonal rise is determined to a large extent by the time of commencement. In England and Wales, as a whole, the seasonal rise begins early in the year, and the outbreak exhausts itself by the end of the first quarter. In a large city it seems that if the foci of infection can develop early the disease will spread right through the community, but if the outbreak is delayed then the disease is generally not so widespread and may die out before some areas have been invaded. Twice during the war the probable course of an influenza epidemic has confounded the prophets. In the early period it was thought that the ideal setting for influenza to assume epidemic if not pandemic proportions was provided by the conditions of work over long hours, often in the black-out, with little or no ventilation, and by the conditions of life due to air-raids, nights spent by people crowded in a deep shelter or exposed to cold and damp in an Anderson or surface shelter. It was also feared that food rationing, particularly the scarcity of protective foodstuffs, might raise the incidence of nasopharyngeal infections by lowering resistance. But no large outbreak occurred; in fact the usual seasonal rise was below the average. The numbers of deaths in the great towns were 5,510, 2,993, and 1,544 during 1940–2, compared with 8,341 deaths in the last epidemic year of 1937. The next occasion for misgiving was in the autumn of 1943, when influenza began to rise sharply some two months before the usual date. During the 49th and 50th weeks there were 2,263 deaths in the 126 great towns, compared with 50 to 72 deaths in these weeks during the preceding four years. From this date the outbreak subsided quickly and had practically died out by the time the usual maxima occurred. Although the number of deaths in the great towns was slightly larger than the number in the preceding wartime outbreaks the epidemic was notable only for its freakish appearance in time.

To predict an influenza outbreak, especially its severity, is not possible. An attack of some notifiable diseases confers immunity, and there is some kind of equilibrium of susceptible persons in the population; the more the equilibrium is disturbed by increasing the number of susceptibles the greater the epidemic that follows. This indication of the possible size of an outbreak is denied us in the case of influenza. In the first place the numbers attacked are unknown, and, secondly, it is doubtful whether an attack of influenza has any effect on the chance of contracting the disease during a subsequent outbreak. The evidence whether an attack of influenza confers any lasting immunity is conflicting; instances have been quoted in which those attacked in one epidemic escaped very lightly in a later outbreak compared with those who were unattacked in the first. Other experiences have shown the reverse—i.e., those attacked in the first outbreak suffered more severely in the subsequent epidemic. From the periodicity of influenza and the general environmental conditions now prevailing the odds would appear to be weighted in favour of an outbreak of epidemic proportions in the spring. It is not likely that the level of 1918–19 will be reached, since the last two great pandemics of 1889–90 and 1918–19 had a summer epidemic; we therefore have no reason to suppose that a pandemic will first appear in the winter.

HOSPITAL NURSES: A NEW DEAL

The seriousness of the nursing shortage has led the Government to inaugurate a campaign to attract nurses and domestic workers to hospitals. The number of women needed for the present nursing services of the country—not hospitals alone—is about 240,000, and the Ministry of Health has stated that on the basis of notified vacancies there is a shortage of something like 34,000 nurses, mostly in hospitals; there are also immediate vacancies for 12,000 domestic workers in hospital, mainly women. Many wards and even some institutions have had to be closed because staff was not available. This does not mean that there is a fall in the rate of recruiting for nursing, or that present numbers are not being maintained; it means that the demands for nursing service in many fields, including school and industrial nursing, are continually growing, and are likely to grow still more with the coming of the National Health Service, bringing about, as it must, a reshaping, and to some extent an expansion, of hospital resources.

The question of domestic workers in hospitals is closely bound up with the nursing question, for there can be no doubt that one reason for the shortage of nurses is that they are required to spend so much time in domestic work, to the disadvantage of the training they had hoped to receive and their prospects of professional promotion. This is probably one of the reasons—no doubt there are others—why so many candidates for the nursing profession fail to stay the qualifying course. Other reasons are the relatively low pay and the restrictive conditions under which nurses have had to work. They have been subject to a discipline which does not apply to other professional women.

The Government has frankly recognized the position. A publication entitled *Staffing the Hospitals: An Urgent National Need*[1] has been issued by the Minister of Health, the Secretary of State for Scotland, and the Minister of Labour. The proposals which it announces for a new standard of nurses' pay and conditions of service put into effect recommendations of the Athlone and Alness Committees; they are also an endorsement of a number of suggestions put forward in a recent memorandum by the Socialist Medical Association. It is, of course, admitted that whatever is done now to improve the nurse's lot will make little difference to the immediate situation: it will not produce nurses by magic to deal with a serious epidemic should such a calamity arise this winter. Emergency arrangements are being made in view of such a possibility. The military authorities have agreed to release 2,000 suitable members of the Women's Auxiliary Services who will volunteer for training as nurses; these will be released under the demobilization Class B, as will also 1,000 women with experience of institutional cookery who will accept employment as hospital cooks. It may be hoped that with the demobilization of large numbers of women from the Services in Class A many of these also will be attracted to a nursing career. There has not been, and apparently is not to be, any "direction" to nursing. The "directed" person is liable to be an unsatisfactory occupant in any sphere, and especially so in nursing.

Two general codes have been worked out by the Government and representatives of all the organizations and interests concerned: one of them for the conditions of service of hospital nurses and midwives, and the other for those of hospital domestic staff. They are offered as the reasonable minimum to be aimed at in all hospitals. Of the improvements proposed some are already in effect in progressive hospitals; some can be brought into operation at once; but others, such as the requirement that nurses shall be free from all domestic work in hospital, obviously depend upon the sufficient recruitment of domestic staff; and others again, such as the accommodation in nurses' homes, must await building labour and release of materials. But it is laid down that it should be the aim of every hospital authority to institute immediately, or as soon as may be, such of these conditions as are attainable in present circumstances and are not already in force.

The first section of the nursing code relates to training. It states that nurses undergoing training should be regarded primarily as students. Training schools should have a preliminary training school—perhaps for more than one hospital—in which the student or pupil assistant nurses would have preliminary instruction before entering the hospital ward. Salaries should be in accordance with the agreed recommendations of the Nurses and Midwives Salaries Committees. The Nurses Salaries Committee for England and Wales has recommended the following scales: Ward sisters, £160–£260; staff nurses, £120–£180; assistant nurses, £90–£160, in all cases excluding the value of board, lodging, and other emoluments, which in the case of ward sisters is computed at £120, and in the case of the other grades at £100. These figures are from £40 to £60 above the existing minimum. Salaries for nurses in sanatoria and other institutions for the tuberculous will be £10 above these scales throughout, and special service allowances will be payable for continuous work in such places. In Scotland the salaries appear to be the same, except for assistant nurses, which begin at £80. Other provisions in the code are adequate pensions on retirement (schemes for interchangeability of pension rights are under consideration); a working time consisting of a 96-hour fortnight, whether on day or night duty; hours of duty for nurses and midwives to include the time they spend in lectures and tutorial classes; a minimum of one complete off-day a week, periodical week-end leave of absence, and four weeks' leave a year, with pay, apart from sick leave. All hospitals should have a definite scheme of health supervision for nurses for which a senior physician is responsible. Nurses should have a medical examination on admission, and periodical examinations; they should have careful instruction at an early stage in training about the facts of infection; regular consultation hours should be fixed for nurses, who should be able to approach the physician for a private interview if they so desire, and there should be suitable and adequate sick-bay accommodation. Certain standards are laid down concerning meals and nurses' homes. A relaxation of tiresome and unnecessary restrictions is urged upon hospitals. Recreation and social activities should be encouraged. At mealtimes nurses should be regarded as being off duty. There will be an end of the boarding school-*cum*-nunnery idea which has clung about nursing for too long. A qualified and experienced warden—not necessarily a nurse—should be in charge of the nurses' home. In every hospital there will be a nurses representative council, with a balanced representation of the different grades, and a staff committee for domestic workers. A National Joint Council for employers and employees in the hospital service has been established.

---

[1] H.M. Stationery Office. (3d.)

Meanwhile to meet the immediate situation a national reserve of nurses is to be formed. Nurses giving up regular work on marriage or for other reasons will be asked to enrol so as to be available for recall in emergency. There will be no barrier to the employment of married nurses, and it is proposed to offer work to part-time nurses so long as the present shortage exists. Male nurses—men who have had nursing experience in the Forces—are to be encouraged, and a grade of ward orderlies is desired in the large hospitals.

The new Government publication, in its note of urgency, conveys a very different impression from the original White Paper on a National Health Service, which dismissed nursing in a sentence or two as one of the "ancillary services" which ought to go with medical care. The three Ministers declare that the situation is extremely serious and is likely soon to become critical unless thousands of new recruits can be obtained quickly.

> "If they are not obtained, large numbers of people urgently requiring treatment will be unable to gain admission to hospital and many patients in hospital will not receive the attention they need. The Government therefore appeal to all men and women who either have experience in this work or who feel that they might do well in it—and particularly to young people who are at this moment thinking about their choice of a career—to come and play their part in this great field of service. . . . The adequate staffing of the hospitals is an urgent national need. It is vital to the successful operation of the new National Health Service. It must be met."

The nation is now paying for its acquiescence for too long in the idea that because nursing exacts from those who enter it a particular devotion they may therefore be underpaid and overworked and subjected to harsher restrictions than pertain to other callings. It is to be fervently hoped that the new realization has not come too late.

PENICILLIN IN BACTERIAL ENDOCARDITIS

The treatment of subacute bacterial endocarditis with penicillin was begun in this country early in the present year, and in a letter to the *Journal*[1] the secretary of the Penicillin Clinical Trials Committee recently reported its early results. These pointed clearly to the need for prolonged treatment: a standard total dose of 5,000,000 units had been given at the rate of 1,000,000, 500,000, and 250,000 units per day, and the percentages of patients who had died or relapsed were 95, 66, and 33 respectively. The policy announced for the future was continuous treatment for 28 days, the daily dose required being the subject of further study. Even more prolonged treatment is advocated by A. L. Bloomfield, C. D. Armstrong, and W. M. M. Kirby,[2] whose policy has been to continue without interruption for six or preferably eight weeks. The initial dose was 200,000 or 300,000 units daily by intravenous drip; later a smaller dose—120,000 to 200,000 units daily—was given by three-hourly intramuscular injections. No heparin was administered. In the treatment of each patient about 10,000,000 units were therefore used. Eleven cases so treated are fully described. All experienced a rapid subjective improvement, and the blood culture became negative, usually as early as the second day of treatment; with the exception of a single patient who died of acute heart failure on the fourth day, every patient had numerous blood cultures both during and after treatment, and none was positive after the fifth day. The temperature fell rapidly in most cases, although in one with a streptococcus abnormally resistant to penicillin *in vitro* the fall was delayed for three weeks, and in others minor degrees of fever, continuous or occasional, were common. Changes in the urine were followed by repeated Addis counts: the degree of microscopic haematuria diminished very slowly, and it had usually not ceased at the end of treatment or even at the last follow-up. There has been no recurrence of infection in any of the 10 patients who completed the course of treatment: 7 are well and at work, while 3 developed heart failure, 1 having already died of this. It is of some interest that these three patients had marked electrocardiographic changes on admission. This series, although short, probably represents fairly what penicillin will do in this disease. The cases were to some extent selected. Results will be worse if treatment is begun at a very late stage or after heart failure has developed; they also depend on the sensitivity of the infecting organism: two other patients are mentioned, one infected with a highly penicillin-resistant streptococcus and one with "influenza bacilli" (presumably *H. para-influenzae*), the course of whose illness was entirely unaffected by penicillin. In the absence of such unfavourable features the infection can evidently be overcome, but in order to achieve this result a prolonged continuous course is necessary, and the minimum of six weeks advocated here is no light undertaking. To embark on such a course without the assurance that it can be carried through to the end—and this means, among other things, first-rate nursing and gaining the patient's co-operation—may be to do ultimately more harm than good.

What neither penicillin nor anything else can do is to repair gross valvular damage. A certain proportion of these patients will always die of heart failure in spite of the valvular infection having been overcome; it is indeed even likely that the shrinkage and fibrosis of vegetations, particularly on the aortic cusps, will render the valve even more grossly incompetent than it was before. Necropsies on two such patients are fully described by P. Rosenblatt and J. Loewe[3]; they had been "cured" of subacute bacterial endocarditis by combined treatment with penicillin and heparin, but died from progressive cardiac failure four and five months later. The aortic valves in each case were so grossly deformed that nothing approaching closure was possible. Histological study confirmed that the infection had been eradicated. One of the cases treated by Dolphin and Cruickshank[4] also came to necropsy because of death from heart failure after successful treatment with penicillin of an acute bacterial endocarditis.

THE CASE FOR NURSERIES

The National Society of Children's Nurseries (117, Piccadilly, W.) has published in leaflet form a memorandum prepared for the Royal Commission on Population. This sums up nearly forty years of experience and applies it to current problems. The Society states at the outset that it stands for family life, and takes the view that nurseries are an extension of the home and not a substitute for it. Then follows a long list of those who already use or will need nurseries. This includes mothers who go out to work: those who work to supplement the family income; widows; mothers whose husbands are disabled; and the professional woman who wants to start a family without sacrificing her career. The case of the professional woman is of special interest, for they will demand high standards in nurseries, and with the shortage of domestic help this is probably the very solution for a career and a family together. Already some institutions have started a day nursery where the children of the medical staff and the visiting domestic staff are looked after during working hours. Another group is that of mothers who have no help in the house; the mother in chronic ill-health; the mother with a new baby and in need of care for her toddler; and the mother faced with an emergency. In general the memorandum stresses the importance of leisure time to mothers, for their mental refreshment, and also the value of making it possible for man and wife to go out together. For the children it is claimed that the effect of nurseries is good, because they develop under expert care and medical supervision. Mothercraft training is also available through the nurseries, not only for the staff in training, who are the mothers of to-morrow, but also for the mothers who leave their children and are inspired to apply in their own homes what they learn in the nursery. The memorandum goes on to face the common criticisms. As regards infection it states: "The health record of the nurseries has in general been good." A letter, printed in the appendix, from the medical officer of health for Salford is a strong answer to those who claim that nurseries foster infection or a sense of parental irresponsibility. On both charges he claims "quite emphatically that these dangers are entirely theoretical." "Nurseries are required," comments the memorandum, "not in order to take away from parents the responsibilities which should be theirs but to put them in a position to carry out those responsibilities." Other means of easing the strain of family life are enumerated, and they are found wanting in some essential respect. Lastly the cost—"nurseries cannot be cheap"—but it is claimed that no expenditure could constitute a better investment or one which would pay richer dividends. The National Society of Children's Nurseries puts up a strong case, devoid of emotional argument and worthy of close study. It claims that the continuation of a nursery service is one of the essential means for improving the quantity and quality of the future generation.

MEDICAL BENEVOLENCE

Sir Arnold Lawson, who has taken the place of the late Sir Thomas Barlow as President of the Royal Medical Benevolent Fund, has written a short review of the position of the Fund at the end of the war. During the last seventeen years—apparently the year 1927 is taken as the starting-point, because it was then that Sir Thomas Barlow made his first Christmas gifts appeal—the book value of the investments of the Fund has risen from £109,428 to £307,248, the subscription income from £7,645 to £19,292, including in the latter figure the income tax recovered under deeds of covenant, and the charitable distribution from £11,916 to £25,284. The criticism has often been levelled at the Fund that it helps too many beneficiaries by means of very small sums and that it would be better if it helped a smaller number more adequately. Sir Arnold Lawson says that it is planned to give every case a minimum allowance of 30s. a week after the rent has been paid. In the case of old age pensioners any action which the Fund can take is often complicated by the means test applied to non-contributory persons, who cannot draw their old age pension if their total income amounts to more than £91 5s. per annum—a wholly inadequate sum in these days but one which the Fund can do nothing to improve unless it disregards the old age pension, which would be an expensive procedure. The question of Homes for old people who cannot look after themselves has been engaging the attention of the committee for a long time, and it is hoped to report substantial progress next year. It is a large undertaking, entailing the expenditure of a considerable capital sum, but the new President feels that the experiment will succeed and that a gap which has long been obvious will be filled. A tribute is paid to the honorary local secretaries, who number 215. Regret was expressed at the resignation, owing to ill-health, of Dr. C. O. Hawthorne, who for many years presided over the Case Committee, which is the medium for all the charitable distributions. Donations for the Christmas Gifts Fund should be sent to the Secretary, R.M.B.F., 1, Balliol House, Manor Fields, Putney, S.W.15.

NEW QUARTERLY JOURNALS

Next year the B.M.A. is to publish three new special quarterly journals: the *British Journal of Pharmacology and Chemotherapy*, the *British Journal of Social Medicine*, and *Thorax*.

The first is to be published in co-operation with the British Pharmacological Society, and the third with the Association for the Study of Diseases of the Chest. The proposal for publishing the second journal came from Brig. F. A. E. Crew, Prof. Lancelot Hogben, and Sir John Orr. Discussions for launching these new periodicals have been going on for the past two years, but it is only now that licence for publication has been obtained. Papers for the first journal should be sent to Dr. H. R. Ing, Department of Pharmacology, Oxford; for the second, to Brig. F. A. E. Crew, F.R.S., the Usher Institute, Warrender Park Road, Edinburgh, 9; and for the third, to Mr. N. R. Barrett, F.R.C.S., 2, Dorset Street, London, W.1.

Dr. Cecil Wall will deliver the Fitzpatrick Lectures before the Royal College of Physicians of London on Tuesday, Dec. 11, and Thursday, Dec. 13, at 5 p.m. at the College, Pall Mall East. Subject: "The History of the English Medical Profession—(1) the Eighteenth Century, (2) the Nineteenth Century."

The Council of the British Medical Association has decided to extend the facilities for borrowing books from the Library to members serving with Occupation Forces, and other official organizations, in the Continent of Europe. This is an experiment, and its continuance will depend upon the various factors applicable to conditions prevailing on the Continent in so far as loss and damage to books are concerned. The ordinary rules as to the borrowing of books will apply, with an extension for time taken in transit. No deposit will be required. Applications for books should be made to the Librarian at B.M.A. House, Tavistock Square, London, W.C.1.

The Central Medical War Committee has been informed of a further acceleration of the rate of release of R.A.F. medical officers. In addition to age-service groups 21 and 22, Groups 23, 24, and 25 will be released during December, 1945.

THE PROBLEM OF RICKETS

The British Paediatric Association in a six-page printed memorandum on rickets, which has been issued by the Ministry of Health and the Department of Health for Scotland to medical officers of health for the information of their medical staff, health visitors, midwives, and district nurses, finds that rickets as a general cause of ill-health among babies in England is now nothing like what it was of old; in fact it is no longer a common disease in this country. At the same time rickets is preventable, and therefore there is no reason why it should occur at all. It is the duty of all who are concerned with children to see that it disappears completely.

The memorandum is arranged under three main headings: aetiology, diagnosis, prophylaxis and treatment. In view of the fact that in the British Isles, owing to a relative lack of sunshine, rickets—a metabolic disorder—must be regarded as primarily a nutritional problem, the memorandum stresses that if a deficiency of vitamin D is avoided the condition will not occur. It has been established by scientific evidence that vitamin D supplied in adequate amounts will prevent rickets. If the disease is actually present it can be cured by supplying vitamin D, thus overcoming the deficiency which has caused it

Diagnostic Difficulties

The diagnosis of rickets presents problems which are discussed at some length. The gross findings so commonly met with in bygone times are rare to-day, and whereas the diagnosis was formerly easy because of the florid form in which the disease presented itself, the clinical diagnosis is apt to be extremely difficult now, owing to the mild signs present in the stage at which it is desirable to detect the disorder and prevent its further development. Where only minor degrees of bony change exist, clinical diagnosis of rickets may be impossible. Can radiology solve the problem, and if so to what extent? "Certainly radiology is of great help and has become increasingly important in the recognition of the milder types of the disease now encountered, but it must not be used to the exclusion of clinical examination. . . . For diagnostic purposes a careful history and clinical examination, together with *x*-ray investigation, while not yet yielding perfect results, will give the most useful information that can generally be obtained at the present time; but this should be supplemented in doubtful cases, whenever possible, by an estimation of the blood phosphatase, for the limitations of both clinical and *x*-ray examinations must not be lost sight of."

Prophylaxis and Treatment

While the diagnosis of rickets is clearly not easy, its prevention and treatment give rise to no particular difficulties, and are in fact simple. To guard against dietary deficiencies, and because breast-feeding is no certain preventive of rickets, the memorandum recommends that babies, however fed, should receive a supplement of vitamin D. Pointing out that, broadly speaking, a daily intake of 500 to 800 international units of vitamin D should prevent rickets throughout infancy, it mentions that cod-liver oil *B.P.* contains 330 i.u. per drachm, while the Ministry of Food's cod-liver-oil compound contains 750 per drachm. "A cod-liver-oil and malt mixture should not be employed as a prophylactic measure against rickets. Its actual content of cod-liver oil, and therefore of vitamin D, is usually small, and it only engenders a sense of false security. For the same reason it should be remembered that cod-liver-oil emulsions contain only 30 to 50% of actual cod-liver oil."

Rickets can occur in a baby before its birth, when the diet of the mother is of vital importance for the child, but the disease is more frequently found in the early years of life, when growth is more rapid. The fact that rickets can be completely avoided by the proper use of simple preventive measures goes far to offset the difficulties associated with diagnosis. In treating active rickets ultra-violet irradiation could be combined, when practicable, with oral administration of vitamin D, the latter in larger doses than when employed for prophylaxis. The carbon-arc lamp is at present by far the most satisfactory source of ultra-violet light for treatment of rickets. Infants who have started to walk should be kept off their feet during the first three or four weeks of treatment.

The memorandum recalls that a special inquiry, carried out by the British Paediatric Association by arrangement with the Ministry and the Department during the war, yielded no evidence that wartime conditions had given rise to an increase of rickets.

THE DISCOVERY OF X RAYS

RÖNTGEN AND PURE SCIENCE

The commemoration of the fiftieth anniversary of Röntgen's discovery of *x* rays[1] was continued in a joint meeting of all participating societies which was addressed by Sir Lawrence Bragg, with Sir Henry Dale, P.R.S., presiding. Sir Lawrence Bragg spoke of Röntgen's discovery in relation to pure science. He quoted from a speech by Sir J. J. Thomson in 1916 at the foundation of the Department of Scientific and Industrial Research, in which he had pointed out that *x* rays were not discovered as the result of research in applied science but of research in pure science, made with the object of discovering the nature of electricity. The experiments which led to the discovery seemed as remote from humanistic interest as could be imagined. Research on the lines of applied science would doubtless have led to an improvement and development of older methods, but research in pure science led to an entirely new and much more powerful method. To use J. J. Thomson's words, applied science led to reform, pure science to revolution. Röntgen's discovery of "rays which I will call *x* rays for short"—to quote Röntgen's original paper—was no chance hitting on something which might have been rather different; the only possible condition in which *x* rays could have been produced was the condition of a discharge tube where the electrons had a long run, a high potential of 50,000 volts or so, and something for the electrons to hit at the end so that they produced the ray. Sir Lawrence Bragg said that he had no idea until he came to read Röntgen's original paper how far he went and how ingenious he was in that contribution. One of the first consequences of Röntgen's discovery was the stimulus it gave to researchers at Cambridge—Rutherford and others—on the ionization of gases which led to the new physics and the work on the structure of the nucleus and all that had resulted therefrom. It was difficult to think of another single discovery which had led to such vast results.

Other commemorations in London during the second week of November took place under the auspices of the Royal Society, the Royal College of Surgeons of England, the Section of Radiology of the Royal Society of Medicine, and the Institution of Electrical Engineers. Most of the addresses delivered were in reminiscent vein.

JUBILEE LECTURE IN EDINBURGH

The discovery and early history of investigation of *x* rays was the subject of the first of four Keith lectures delivered in the University of Edinburgh on Nov. 12 by Prof. Norman Feather. The course was arranged by the Royal Scottish Society of Arts to mark the jubilee of the discovery of *x* rays. The other lecturers are Dr. Robert M'Whirter, Edinburgh, and Prof. G. D. Preston, Dundee.

Prof. Feather, after discussing the investigation of the phenomena involved in the passage of electricity through rarefied gases from the time of Faraday onwards, said that in 1895 Röntgen discovered a new and quite distinct effect outside a cathode-ray tube: an invisible radiation proceeding in straight lines from the points of impact of the cathode rays on the wall of the tube, capable of affecting a photographic plate or a fluorescent screen and of throwing partial shadows of solid objects placed in its path. Röntgen discovered this phenomenon as it were accidentally, but he was fully aware of the importance of his discovery. From the point of view of pure physics the outstanding contributions at that stage came from Cambridge. J. J. Thomson and M'Clelland discovered the ionizing power of the rays, and Thomson and Rutherford, as the result of a brilliant series of experiments, within a few months formulated the basic ideas which were still used in all discussions of gaseous conduction. Then Thomson, more fully than, but perhaps not quite so early as, certain Continental physicists, established the nature of the cathode rays (1897), and Stokes put forward a theory, which was recognized as essentially correct to-day, of the mode of production of *x* rays by the impact of the cathode rays on matter.

SPECIAL FIELDS OF NURSING

Nurses are required to give a year of special service to the State after qualification, and it has been decided that the fields of service for State-registered nurses qualifying through the October, 1945, examinations in Great Britain will be as follows: (*a*) Nursing of tuberculosis, mental illnesses, and chronic sick. (*b*) Training as a midwife, which at present carries an obligation to practise midwifery for a year after passing Part II of the C.M.B. examination. (*c*) Training with District Nursing Associations. (*d*) Employment in certain E.M.S. hospitals. (*e*) Nursing in a cancer hospital. (*f*) Nursing or training in a hospital specially devoted to ophthalmic or E.N.T. patients. (*g*) Nursing in infectious diseases hospital. (*h*) Nursing in a hospital affiliated to a complete training school. (*i*) Training for Part I of the C.M.B. examination, which may be preceded or followed by six months' service in any other special field.

NURSING OF TUBERCULOUS PATIENTS

In a circular letter to hospital authorities, dated Oct. 12, the Minister of Health calls attention to the continued shortage of nurses for patients with tuberculosis, resulting in the closure of many beds which could otherwise be made available for such patients. The Minister of Health and the Minister of Labour and National Service are seriously concerned at the present position, and various measures have been taken in an effort to alleviate this. But although such action has undoubtedly helped sanatoria it has not been possible to keep pace with the growing demands. The introduction of mass radiography, for instance, by facilitating the discovery of cases at a stage when they are likely to respond well to treatment, has increased for the time being the number of patients in need of immediate treatment. The estimated shortage of nurses of all grades for tuberculosis beds on May 1, 1945, was 1,909, being a deficiency of 24.2% on establishment.

The Ministers are well aware of the widespread shortage of nurses in all types of hospitals and in the health services generally, and every effort will continue to be made to help employing authorities in this matter. The shortage in the tuberculosis services is, however, especially acute. The number of patients awaiting admission to hospital for treatment for tuberculosis on June 30, 1945, was 4,972, compared with 4,628 on March 31, and the waiting patients include ex-Service men and women and repatriated prisoners of war. In these circumstances the Ministers have decided to appeal to the authorities of all hospitals other than tuberculosis institutions, notwithstanding their own difficulties, to review the nursing staffing of these hospitals and to consider whether in view of the acute difficulties at tuberculosis institutions it is not possible for them to release some of their trained (or assistant) nurses for service in such institutions. Hospital authorities would need the willing co-operation of the nurses whom it was proposed to release for tuberculosis work, but the Ministers are hopeful that if the full facts and the urgency of the need are explained to the nurses they will co-operate.

Regional conferences and discussions have been held to encourage arrangements under which student nurses taking their general training spend part of their time in tuberculosis work. The Minister of Health understands that, following these conferences and discussions, a number of authorities have made, or now contemplate, arrangements (subject to the approval of the General Nursing Council) whereby student nurses taking general or fever training could with advantage be seconded to sanatoria for part of their training. He is anxious that such arrangements should be made more general.

MEDICAL DEFENCE IN SCOTLAND

At the annual meeting of the Medical and Dental Defence Union of Scotland held in Glasgow on Oct 19 it was reported that during the year membership had increased by 345, the number of members now being 5,463, of whom 1,883 are on active service. In connexion with the work of the year it was mentioned that cases have come to the notice of the Union in which errors have been made in administering dangerous drugs. Members are advised to verify the contents of bottles immediately before using them, even though it may also be the duty of some other person to do this. Another piece of advice concerns the desirability of keeping a careful record of consultations, treatment, and appointments, including telephone calls, and all information on the progress of cases. Such records, being contemporary evidence of what transpired at the time, are very valuable in the event of disputes arising at a later date. The council has prepared a model form of assistantship agreement which can be had on application. The working arrangement with the Medical Defence Union and the London and Counties Medical Protection Society has been advanced. An excellent financial report was presented, showing that the Union had been able to strengthen its position notwithstanding the loss of revenue due to waiving subscriptions from members in the Forces.

Reports of Societies

BRITISH ORTHOPAEDIC ASSOCIATION

The annual meeting of the British Orthopaedic Association was held at the Royal College of Surgeons of England on Oct. 26 and 27.

Accident Prevention

Mr. St. J. D. **Buxton**, in his presidential address, reviewed methods of preventing accidents. Fatal accidents in industry had fallen in number, but there had been in recent years a steady increase in all reported accidents. Injuries of the foot and hands were of particular frequency. It had been estimated that the financial cost and production loss from industrial accidents amounted in this country to £70 million a year. Propaganda was needed for the further education of the workman and others. Members of the Association should aid in preventive work by inquiry as to the exact causation of accidents and in other ways should effect closer co-operation with those concerned with industrial medicine.

Prof. T. P. **McMurray**, in the course of a fascinating account of the historical background of Hugh Owen Thomas, went on to describe the classical splint which Thomas, and his disciples, called the "bed knee splint." The efficiency of this appliance, which Thomas evolved in his own workshop, was emphasized. Almost all the improvements and alterations since made had been tried out by Thomas and discarded. The details of the splint's construction, measurement, and application were described. Simplicity in design meant that there was little to go out of order. There should be no cause for anxiety given care in nursing and surgical faith and knowledge.

Congenital Dislocation of the Hip

Prof. J. **Leveuf**, of Paris, described investigations, based upon arthrography and operation, which showed that there was a complete difference between congenital subluxation and congenital dislocation of the hip. He differed from the commonly accepted view that subluxation was a preliminary stage leading to dislocation. In arthrograms of dislocation the limbus produced by the upper portion of the cotyloid ligament or cartilage was visualized as a downward projection causing the usual hour-glass contraction; in subluxation this shadow was never found, for the limbus was pushed upwards and compressed against the ilium. In dislocation the head of the femur was small and the ligamentum teres persisted; in subluxation the femoral head was large and the ligamentum teres absent, and there was no other interposition of soft tissue. Anteversion of the femoral neck was an early finding in subluxation; it was a late or secondary deformation in dislocation.

In treatment, Prof. Leveuf stressed the need to get a hip in which the femoral head and the acetabulum conformed. Closed reduction was only suitable under the age of 2. Afterwards he favoured operation, and in those cases requiring reconstructive work to restore the bony conformation he favoured a transtrochanteric intra-articular approach, in which osteotomy of the femoral neck was carried out, if necessary, and the acetabulum deepened by turning down its roof and the insertion of a graft above it.

Mr. J. S. **Batchelor** reviewed the problem from the point of view that congenital dislocation of the hip was an external rotation–adduction deformity with three stages of severity. Treatment consisted in correction of soft-tissue contracture by gradual abduction, followed by manipulative reduction and reversal of the deformity with encouragement of normal development by function. For this purpose he used knee plasters joined together by a cross-bar, the hips being held in abduction and internal rotation but otherwise free to move in flexion and extension. For cases showing redislocation, anteversion, and valgus of the femoral neck, osteotomy to reduce these deformities was carried out after replacement of the head in the acetabulum.

In the discussion which followed, Mr. H. A. T. **Fairbank** remarked that Prof. Leveuf appeared to do open operations more often than was thought necessary in this country, yet his results were excellent. His own view had been that hitherto the problems of anteversion and valgus had been overstressed: evidently he was wrong. Anterior transposition or anterior dislocation he thought should be left alone.

Prof. Harry Platt, speaking from more than 30 years' experience of nearly 500 cases, strongly supported Prof. Leveuf's view that subluxation and dislocation were two distinct morphological entities and that future contributors to the subject should classify cases accordingly. He also believed that the femoral heads were naturally placed posteriorly in many cases and anteriorly in some. He denied that the former could be forced into the latter position, and he also believed that the position of marked internal rotation for fixation was dangerous. Mr. G. R. Girdlestone expressed anxiety over the risks of avascular changes in the femoral head after extensive intra-articular operations.

Sir Reginald Watson-Jones, reinforcing Prof. Platt's views, thought that there were a multiplicity of morphological types. He distinguished three main types from the point of view of treatment. The first were those hips which were reduced in full abduction, and after a year remained reduced. The second group, after a year of abduction, tended soon to subluxate on being allowed to kick about in bed. In the third group, despite full abduction the heads were never fully reduced to the bottom of the acetabulum. The second and third groups required operative treatment, and the last one should be recognized early and operated on promptly. He believed that there was less risk of osteo-arthritis in cases with incongruity of capital and acetabular form than there was in those with avascular changes in the femoral head. For this reason he felt that a long period was needed to permit of judgment of Prof. Leveuf's results.

In reply Prof. Leveuf said that true dislocation was more difficult to reduce by non-operative methods; the ease of "reduction" in subluxation was deceptive, and the results by this method likely to be disappointing. If a state of subluxation continued, osteo-arthritis would be certain to occur. He stressed the value of the arthrogram, not only for diagnosis but also as the most satisfactory test for reduction. He was convinced of the value of his complete operation. In 202 cases in which he had done open operations of all kinds he had had only one case of necrosis of the femoral head. The secret he felt was that there was no interference with the circulation which entered the femoral head from the soft tissues below the femoral neck.

Orthopaedics in Medical Education and in Regional Hospital Services

Starting from the definition by Robert Jones that orthopaedics is "the treatment by manipulation, operation, re-education, and rehabilitation, of the injuries and diseases of the locomotor system," Prof. Harry Platt (Manchester) reviewed the evolution of specialism in surgery, or differentiation, as a changing pattern. There were two fundamental requirements: each surgical specialty must continue to advance the general craftsmanship of surgery, and—of even greater significance—it must contribute to general ideas. Richness of technological advances would not compensate for poverty of ideas or vision. The recruitment of men and women trained in scientific and historical methods and with standards of high scholarship was needed for the preservation of vitality in the differentiated fields. Prof. Platt regarded abdominal surgery as the "romantic" movement in surgery with its growth during the twentieth century; orthopaedics, embracing a large part of the general surgery practised by the nineteenth-century surgeon, as being rooted in the classical period. The automatic right of the abdominal surgeon to assume leadership in the affairs of surgery could no longer be admitted. A plea was made for more satisfactory integration of undergraduate teaching in orthopaedics; not to instil the details of complicated techniques, but to introduce and to explain to the student the clinical phenomena of the disorders of locomotion, the biological and social background of crippling disease, and the ancient therapeutic methods of rest, fixation, and purposive movement. Orthopaedic teaching must permeate the undergraduate course. In postgraduate education three types of instruction were considered: the training of the orthopaedic surgeon of the future; postgraduate instruction of the short intensive type; and training for higher degrees or diplomas in orthopaedics, the desirability of which was doubted.

In the Regional Hospital Service of the future the orthopaedic services were envisaged as of two types. In an area with a population of 150,000 one orthopaedic-accident surgeon would be associated with two general surgeons in the key hospital, his time being devoted predominantly to the problems of trauma. Such an area unit would not supply enough examples of the rarer orthopaedic problems to enable the peripheral orthopaedic surgeon to become expert in their handling. Certain types of work—for example, the long-term care of the crippled child and of surgical tuberculosis—were already in effect regionalized by State action. Some of the more specialized orthopaedic problems must flow on the one hand to university centres and on the other to county orthopaedic hospitals. The link between central and peripheral orthopaedic departments must be preserved through the association of the staffs of one with the other.

Other Communications

Island Epidemic of Poliomyelitis.—Prof. H. J. Seddon (Oxford), in describing an epidemic in Mauritius, found that the evidence on this occasion strongly suggested the transmission of the disease through personal contact. He gave a picturesque account of the conditions of this colony with its mixed population, and of its difficult social and economic state. Later he outlined a scheme for the advancement of orthopaedics in the Colonies, where great opportunities existed for young orthopaedic surgeons keen to tackle a pioneer problem of great importance to the welfare of vast areas. The appointment of such men should be part of a scheme that related them to orthopaedic establishments at home, and through which, after three years or so, their future security would be assured.

New Principle in Splint Construction.—Mr. Norman Capener (Exeter) demonstrated two splints based upon existing types used for the substitution, or support, of deficient muscle activity, as in the familiar toe-raising spring for paralytic equinus. Such appliances usually had springs attached to a rigid framework, whereas the present appliances were themselves constructed into "lively" springs. The appliance for drop-foot in which the upright element (either single or double) was suitably tempered and coiled at the level of the ankle-joint had the advantage of permitting a certain degree of lateral mobility in the foot. The second splint, used in ulnar intrinsic paralysis, was based in its clinical application upon an original design produced by Mr. A. M. Hendry and his co-workers at Derwen, Oswestry, and also possessed great advantages of "liveliness" over previous ulnar splints, which only rigidly maintained flexion of the knuckle-joints.

Arthrography of the Knee-joint.—Squad. Ldr. E. Somerville demonstrated an improved technique for the diagnosis of lesions of the knee-joint by air arthrography. A series of 331 knees had been investigated and a very high degree of accuracy in diagnosis achieved. Success depended upon precision in attention to the following details: examination of the joint under anaesthesia followed by injection of filtered air until it was full; the intra-articular pressure was then temporarily increased by bandaging over the suprapatellar pouch; positioning of the joint over a curved cassette; the use of a sinus cone; and accurate direction of radiation in seven tangential planes. Beautifully clear radiographs were shown.

The Fractured Femur.—Three different methods of treating simple extra-articular fractures were discussed.

Mr. R. G. Pulvertaft (Grimsby) dealt with fractures of the trochanteric region, for which he preferred the Hamilton Russel method of balanced traction without splintage. The advantages claimed were efficient traction with the joints in optimum position, complete comfort, muscular relaxation and well-being; the maintenance of muscular condition and knee-joint movement; and reduction of chest and decubitus complications owing to freedom to sit up and change position. Careful supervision was essential. There were none of the disadvantages of any other method of treatment and it had given a high proportion of favourable results.

Major John Charnley, discussing the treatment of fractures of the shaft by fixed skeletal traction, stressed the importance of controlling lateral angulation and of maintaining immobilization of the fracture, and therefore of the knee-joint, for fully eight weeks. Special apparatus, which he had devised, was used in conjunction with the Thomas bed knee splint; it was designed to give precision, and to be relatively foolproof after accurate adjustment by the surgeon. The essentials were traction upon a pin through the upper end of the tibia, pulling along a line posterior to the femoral axis, with the femur supported across a specially shaped padded metal fulcrum. Lateral control was achieved by pads screwed on to adjustable fitments to the lateral bars. Early movement of the knee was not only inadvisable, it was unnecessary.

Mr. G. R. Fisk proceeded by a completely opposite course, establishing early movement by the use of skeletal traction in a flexing splint made from a Thomas splint sawn off at the knee level and joined by an articulation of the Pearson type.

Mr. V. H. Ellis in a study of 420 recent femoral shaft fractures supported the advocates of early knee movement. The causes of limited flexion were intra-articular adhesions, fixation of the quadriceps, scarring in the region of the fascia lata, especially in high compound fractures, and transfixion of the muscle by spicules of bone.

Actinomycotic Infection of Gun-shot Wounds.—Mr. C. H. Cullen (Winwick) reported upon five cases, in four of which the organism was of an unusual aerobic type. All the cases were very chronic and resistant to treatment. Adequate surgical measures combined with penicillin seemed to be of most use. It was interesting that the latter treatment was beneficial in cases in which concomitant organisms were insensitive to penicillin.

Pollicization of the Index Finger.—Mr. E. W. BINTCLIFFE demonstrated two patients successfully treated by him, in conjunction with Major Kilikian, U.S.A.M.C. In such cases after amputation of the thumb the web space between the index and middle fingers was deepened by dissection. The second metacarpal was divided, allowing the index to be abducted and attached by wire suture either to the remains of the first metacarpal or to the trapezium. The defect created between the new thumb and the middle finger was filled by a skin graft. It was desirable to carry out abduction by traction with a wire transfixing the index. The two patients shown had very good function in the "thumbs" thus produced.

Clinical Photography.—Mr. P. G. HENNELL (of the Metal Box Co. Ltd.) impressed everyone with the need to take seriously this important aid to scientific recording and medical education, and to use adequately the apparatus which recent technical advances had placed at our disposal. He believed that in five years black-and-white photography would largely have been superseded by colour in the production of scientific records. The apparatus which he had used in clinical photography was demonstrated as well as a wide selection of colour photographs of surgical procedures.

PEPTIC ULCER

At a meeting of the Paddington Division of the B.M.A. held at St. Mary's Hospital recently Prof. G. W. Pickering and Prof. C. A. Pannett opened a discussion on peptic ulcers.

Prof. PICKERING regretted that his house-physicians and senior students showed little interest in this condition. As the incidence of peptic ulcer in the general population, he said, was roughly 10% it deserved closer attention. While the cause of the development of peptic ulcers was unknown, various factors which contributed to that development and to recurrence were known. The gastric juice itself, with its hydrochloric acid content, was an essential though not the sole factor. A second factor was the state of the gastric mucosa; and a third, a psychological one, the influence of the mind. Pain was due to the action of hydrochloric acid on the nerve endings at the base of the ulcer. The routine medical treatment for peptic ulcer was: (1) bed; (2) diet which controlled acid—i.e., meals taken at one- to two-hourly intervals, as digestion temporarily reduces acidity; and (3) alkalis, experiments with which had shown that, contrary to common opinion, magnesium trisilicate had a very poor neutralizing effect; in Prof. Pickering's view the most effective agent was the common pharmacopoeial pulv. alk.; (4) removal of anxiety. In spite of treatment ulcers did recur, and recurrences were more frequent in hospital patients than in those in more fortunate circumstances. Factors which contributed were lack of co-operation between the doctor and the patient; difficulty in keeping to the prescribed diet, possibly because of expense; anxiety caused by social conditions; inattention to teeth; and smoking.

Referring to the treatment of complications Prof. Pickering said that haematemesis should be controlled by transfusion and then early feeding; surgery had no place in the treatment of this condition. In cases of perforation, however, surgery was necessary at the earliest possible moment. In pyloric obstruction surgery was also necessary, but where for some reason surgery was not indicated he had seen good results from the aspiration of the stomach night and morning. Prof. Pickering stated that the results of medical treatment of peptic ulcers were, on the whole, disappointing. Patients had to live careful lives to maintain health, and recurrences not infrequently occurred.

Prof. PANNETT said that, although the aetiology of peptic ulcers was unknown, surgery had to work on some hypothesis. There were three theories: (1) Infective: gastric ulceration behaved like a localized infection in that it waxed and waned and had a seasonal incidence, also it was possible that the fibrous tissue which formed round the ulcer was toxic in origin; the infective theory was difficult to prove, as animals did not develop peptic ulcers. (2) Digestive: sites favourable to peptic ulcers were along the lesser curvature of the stomach and in the first part of the duodenum—namely, those parts of the gastro-intestinal tract regularly bathed with acid. (3) Neurogenic: Cushing performed experiments which demonstrated the effect of nervous impulses on the development of peptic ulcers; this was probably due to some "vagus" action. The basis for surgery would therefore seem to be the reduction of the amount of gastric juice produced. The surgeon must remove the pyloric part of the stomach and a large surrounding area, thus allowing a free neutralization of the stomach contents. It had also been found essential to remove the ulcer at the same time.

When considering the results of surgery in cases of peptic ulcers one must remember that the surgeons were operating on those cases which had not responded to medical treatment. He claimed that 87% of cases were cured, and by cured he meant that the patients no longer had to take care of their diet, they could eat anything, and, in short, "did not know they had a stomach." The mortality rate was low—somewhere in the region of 1%.

In the general discussion the chairman, Dr. G. DE SWIET, asked what reliance could be placed on radiology in diagnosis. Dr. JACOB said he found it very difficult to assess when ulcers were cured, especially in the case of duodenal ulcers, when radiology had often let him down. He commented on the fact that closure for perforation seemed to reduce symptoms for a considerable time. Dr. STOWELL had seen the dramatic effect on duodenal haemorrhage of adrenaline by mouth in doses of 1 c.cm. in 10 c.cm. of water. Dr. LONG, speaking from his experience in industrial medicine, stressed the importance of the psychological factor in the production and recurrence of peptic ulcers, and urged that physicians should give more attention to the social background and future of gastric patients. He found ascorbic acid in doses as small as 25 mg. to be beneficial.

Replying to questions Prof. PICKERING said that he considered radiology useful but not infallible. The same applied to gastroscopy. The clinical history was at least as important as radiology. Prof. PANNETT confirmed Dr. Long's observation on the value of ascorbic acid. He wondered whether the common belief that there was a reduction of symptoms following perforation might be explained by the theory that there had been an acute exacerbation of the infective agent which gave immunity for a considerable period. He had noticed that bleeding from gastric ulcers was much more serious in patients over the age of 45. Medical treatment for haematemesis might be worth trying in the younger age groups, but, in his opinion, surgery should be resorted to as soon as possible in older patients.

Major J. MINTON, in a lecture on eye diseases in the East, given at the Royal Institute of Public Health and Hygiene, said that every year, in the spring and late autumn, epidemics of conjunctivitis attacked thousands of infants and children in Iraq, India, and Ceylon. (The Middle East—Egypt, Palestine, and Iraq—has been well known from time immemorial for its high incidence of eye infections, and blindness often resulting therefrom.) The hospitals were crowded with natives who brought their children to the cities. The conjunctivitis was highly virulent and often extended to the cornea, causing severe corneal ulcers which might perforate and lead to blindness of the infected eye. The best treatment for all types of muco-purulent conjunctivitis was local and general treatment with sulphonamides. Penicillin had been used recently with great success: it would save many eyes which, up to a short time ago, would certainly be destroyed by virulent infections. Unfortunately, in the East these modern methods were used but rarely. The native population of the Middle East was also highly infected with trachoma. The disease started in childhood, was very infective to adults, and needed energetic treatment. Within recent years general and local treatment with sulphonamides had proved most successful. Efficient treatment would diminish the incidence of trachoma in the East and the appalling blindness resulting from it. In India and Ceylon the poor often suffered from vitamin A deficiency; in Karachi and Ceylon Major Minton saw many children suffering from this disease which also affected the eyes. In the early stages children and adults complained of difficulty in seeing in the dark. The conjunctiva showed small yellowish areas. The cornea lost its lustre, corneal ulcers appeared, and generally the whole cornea might necrose. The eye might develop a generalized infection, going on to blindness. Intensive treatment with high doses of vitamin A would save the child's eyes if this was started in the early stages of the disease.

At the annual general meeting of the Association of Industrial Medical Officers the office bearers for 1945–6 were elected, as follows: Chairman, Dr. W. Blood; Hon. Secretary, Dr. P. Pringle; Hon. Treasurer, Dr. Patricia Shaw; Executive Committee, Drs. J. A. Amor, J. G. Billington, J. C. Bridge, T. A. Lloyd-Davies, C. L. Potts, and R. S. F. Schilling.

Correspondence

Medical Books for Holland

SIR,—Would you be good enough to allow us space to make an appeal for our Dutch colleagues. There is almost no limit to the kind of help which the Dutch need, but there is one special form of assistance which the medical profession may be able to afford. We are, both of us, members of the Help Holland Council, and are thereby kept in very close touch with that country. Information has reached us that there is need at the moment for small modern medical libraries which can be consulted by the medical students in the training hospitals in Holland. If the depleted ranks of the medical profession of Holland are to be filled, up-to-date medical literature for the students is of vital importance. We suggest that a doctor should look through his shelves to see if he can spare any up-to-date medical, surgical, or scientific books.

Gifts will be greatly appreciated, and should be sent to Help Holland Council, Norman House, 105/109, Strand, W.C.2. —We are, etc.,

Moran.
Alfred Webb-Johnson.

The Teaching of Human Anatomy

SIR,—We have become accustomed of late to hear of plans for reducing the time and the content of the curriculum in human anatomy. It may happen that, with all the younger sciences demanding his attention, the medical student will be forced to effect some economy in the time spent in obtaining first-hand knowledge of the structure of the human body, but it is dangerous to assume that this knowledge is becoming less necessary to those who are to engage in the active practice of their profession.

Probably all will agree that, if any pruning is to be done to the curriculum in human anatomy, it is essential that it should be undertaken by men who are themselves medical graduates and who have specialized in the study and in the teaching of the structure of the human body. Only thus can it be ensured that our future physicians and surgeons will obtain the knowledge necessary for dealing with the everyday problems of their professional work. We cannot contemplate without very real misgivings a state of affairs in which the teaching and examining of medical students in the subject of human anatomy are handed over to anyone not medically qualified or possessing that first-hand knowledge of the structure of man can be attained only by the long apprenticeship hitherto considered as an essential qualification for the tenure of a chair of human anatomy.—We are, etc.,

Debility following Blood Donations

SIR,—During the last six years thousands of lives have been saved by blood transfusion, as articles published in your pages bear witness. The importance of blood transfusion itself as a therapeutic measure, and of specialized products prepared from human blood that are essential for plastic and cerebral surgery, will continue to grow in peacetime. There is at present no adequate substitute for human blood and its products.

I have reason to believe from a small inquiry made during the summer that many donors are most anxious to continue to help their fellows by making a regular blood donation to the national blood transfusion service. I hope that all medical practitioners will realize how essential it is to the health of the community that this service should continue, and will encourage their patients to support it.

At the moment a few donors are bringing letters from their doctors stating that they are suffering from "debility following blood donations." Our prolonged follow-up of numbers of regular donors in the N.W. London area makes me sceptical of this diagnosis of the cause of debility. Haemoglobin estimations made on donors who have given their blood at least three and sometimes as often as ten times in the preceding five years showed that in extremely few instances was the haemoglobin level below 80% Haldane, which has been generally accepted as a safe level above which bleeding might be carried out. In the few instances in which a lower figure was found a course of iron therapy given by the donor's own practitioner immediately returned the figure to normal. Even in those with a level below 80% no general symptoms were noticed by the patients and they were always anxious to continue to give blood. Any donor found on routine examination to have a haemoglobin level below 80% Haldane is now given iron free of charge.

Evidence available on large series of donors elsewhere supports the point of view that blood donations made not more frequently than three or four times a year are without effect on the general health.—I am, etc.,

Oxford. Janet Vaughan.

Morphine as a Prophylactic against Ileus

SIR,—We wish to thank Prof. J. H. Burn for his letter (Nov. 3, p. 622) upon this subject. We believe that the mechanism of neurogenic ileus is an alteration in the gradients of the bowel, and that in "paralytic ileus" there is a general or local flattening of these gradients (see Arris and Gale Lecture, 1945, for details) with general or local distension of the gut. The essential features in the prophylaxis and treatment of the condition are, first, removal of the cause producing altered intestinal gradients, and, secondly, the prevention and relief of distension, which may rapidly become enormous and lead by stasis to severe fluid loss into the lumen and wall of the bowel and to intramural thrombosis and gangrene besides pressure effects on the cardiovascular and respiratory systems.

The value of morphine in the treatment of the condition is still a matter of dispute, but numerous observations are now available showing its action on the human intestinal tract when used in normal therapeutic doses. Plant and Miller (*J. Pharmacol.*, 1926, **27**, 316) demonstrated that morphine acts directly on the smooth muscle of the small intestine and increases tone waves both in size and in frequency. They were able to show on dogs that the increase in tone started in a few minutes and lasted from 5 to 8 hours and sometimes even for 12 hours. This prolonged general increase of tone is associated with a slight increase in the amplitude of segmentation and peristaltic movements, though peristalsis was decreased in rate after the first two hours. The giving of atropine had no effect upon the action of morphine on the gut. Wangensteen (*Proc. Soc. exp. Biol.*, N.Y., 1931, **28**, 434) confirmed these findings in experimental intestinal obstruction, and Dragstedt (ibid., 1931, **28**, 1056) found the same results obtained in peritonitis. Plant and Miller (*J. Pharmacol.*, 1927, **32**, 437) also found a similar effect upon the colon, and showed (ibid., 1926, **28**, 241) that these effects upon the gut continued after every injection of morphine for at least ten weeks; and lastly they showed (ibid., 1927, **32**, 413) that morphine delays the emptying of the stomach by a decrease in both the tone and the frequency and amplitude of its peristaltic waves. Finally, Gruber and Robinson (ibid., 1929, **37**, 101) demonstrated that all these effects take place whatever happens to be the initial tone of the bowel.

These and many similar observations make it clear that morphine produces a long-lasting increase of intestinal tone unassociated with spasm in both the small and the large intestine. True peristalsis is increased for short periods and gastric emptying is definitely delayed. In fact, in addition to its narcotic properties, it possesses all the attributes desirable in a drug for the prophylaxis and treatment of "paralytic ileus," with the exception of a specific action righting altered gradients. The delay in gastric emptying prevents the rapid passage of swallowed gas and stomach contents from adding to the distension, while the increase in tone produced by its action directly on the smooth muscle of the gut aids the prevention of distension and helps the passage of gas and fluids through an area of flattened gradients, and the limited peristalsis engendered is not sufficient to build up local distension greatly in the area of ileus, but it does help to empty the bowel below it. It was for these reasons that we have used morphine in all our cases, and particularly after operations upon the intestine, and the statistics presented do show "that the paralytic ileus rate was lowered after morphine therapy started" and that "the statistical analysis can only be claimed to show that the decrease was greater than could easily be ascribed to chance, and that it was not due to inherent differences in the two series as regards age, parity, and type of operation or indication." We are aware that these statistics are only suggestive, but we would point out that the cases were not handled differently in the two periods in other respects, as Prof. Burn infers, except, of course, for such things as alteration in bread during the war, which has not apparently affected the incidence of ileus in other cases.

Finally, we should like Prof. Burn to comment further on the value of the parasympathomimetic drugs. We have used them in both man and experimental animals, and our observations suggest that they give rise to marked intestinal contractions, which last about 45 minutes; but we have not observed any true peristalsis produced by them or lasting increase of tone. They often give rise to nausea and colic, as well as having definite dangers for the debilitated patient by lowering the blood pressure. It may be that repeated small doses are of value, but their effect does not appear to us to be as satisfactory as morphine, even in cases well enough to tolerate it, and the reaction after its use, especially if it has failed to relieve distension, is often severe, and we have completely given up using it.—I am, etc.,

City General Hospital, Sheffield. JUDSON T. CHESTERMAN.

Penicillin and Rubber Tubing

SIR,—Tubing supplied as of "natural rubber" may be as destructive of penicillin as some synthetic rubbers have been found to be. We have recently tested four samples of tubing from different manufacturers, all stated by the makers to be "natural" rubber. The following method was used.

A weak solution of penicillin was enclosed in a sterile length of each of the tubings for 24 hours at 16° C., and as a control some of the same solution was kept in a glass tube for the same time at the same temperature. Potency assays were then made by the plate method described in the M.R.C. War Memorandum No. 12. The following results were obtained:

Penicillin	*Zone of Inhibition of Staphylococcus*
In glass	10 mm.
" tubing No. 1	9 mm.
" tubing No. 3	6.5 mm.
" tubing No. 4	6 mm.
" tubing No. 5	5 mm.

The conclusion is that this or a similar test should be employed before deciding that any tubing is suitable for use in penicillin administration apparatus, whether this tubing be supplied as a "natural" or as a "synthetic" rubber.—I am, etc.,

E.M.S. Hospital, Bridge of Earn. M. E. MORGAN THOMAS.

Pernicious Anaemia and Cancer

SIR,—I must add strong support to the recommendations of Dr. J. F. Wilkinson (Nov. 10, p. 664) concerning the establishment of haematological clinics for the diagnosis and treatment of persons suffering from pernicious anaemia. Patients who have been injected with many gallons of liver extract over a period of years (often at considerable personal expense) following a doubtful diagnosis of pernicious anaemia are becoming all too common; I have encountered three within the last few weeks. It should be remembered that a high colour index is as frequently a sign of inaccurate haematology as it is indicative of a macrocytic anaemia; furthermore, pernicious anaemia cannot be diagnosed by examination of a blood film, as so many people seem to believe. Additional investigations such as sternal puncture, fractional test meals, reticulocyte and platelet counts, and spectroscopical examinations are easily carried out and should be routine.

It is obvious that unless cases of pernicious anaemia are properly investigated at the outset any conclusions as to the incidence of malignant or endocrine disease are of little value; in fact, one of the three doubtful cases of pernicious anaemia which I mentioned earlier now has a gastric carcinoma. Dr. Wilkinson's cases have been fully investigated before diagnosis, and should therefore provide a very accurate basis for discussion.

The low incidence of malignancy and relatively increased frequency of diabetes mellitus are in agreement with my personal experience, but I look upon the hypothyroid symptoms often met with as part and parcel of the obesity caused by desiccated stomach preparations; the B.M.R. prior to treatment is often very slightly raised.—I am, etc.,

WILLIAM K. TAYLOR,
Broadgreen Hospital, Liverpool. Pathologist.

Significance of the E.S.R.

SIR,—While agreeing with the conclusion of Drs. D. G. McIntosh and D. M. Keay (Oct. 27, p. 584) on the significance of the E.S.R. "that no other test having an error of such magnitude would be tolerated in practice," we would stress the difference between the high degree of possible technical accuracy and the unreliability as a clinical test due to inability to interpret the figures so produced. Medicine is like a seaman with an accurate sextant which he can manipulate mechanically but from which he cannot derive his bearings.

Let us get back to fundamentals. The E.S.R. is a measurement of the rate at which the erythrocytes separate down in a column of blood in which clotting is prevented by an anticoagulant. The rate of fall varies from individual to individual according to the power of the plasma to cause aggregation of the erythrocytes into clumps, which, compared to the single cell, have a greater mass relative to surface area—the larger the clumps the faster the fall. Thus the E.S.R. measures ultimately the aggregating power of the plasma; and, with a technique based on hydrodynamic principles, as a measure of this power the accuracy of the test is high. This aggregating power varies with changes in each of several components of the plasma (protein, lipoid, urea, etc.).

The clinical use of the E.S.R. is based on the assumption that in organic changes in the body there occur changes in the complex of factors which can affect the E.S.R., and that the change parallels the increase and decrease in the intensity of the pathological process. The individual factors may alter in ways which have an opposing effect; each factor may be affected to a different degree in one disease process; any factor may be affected to different extents by different diseases of equal clinical severity. Until there is a means to separate the behaviour of the parts from that of the total complex the interpretation of the E.S.R. must remain uncertain, and with it the present doubtful reputation of the test.

Returning to technique. If this be standardized for anticoagulant, tube length and diameter, temperature, and packed cell volume, and if we take only that portion of the fall/time curve where the velocity is a maximum, we have an *absolute* value which can be subjected to hydrodynamic investigation (Whittington[1]) and which is directly comparable with a similarly produced value in any other laboratory. Every departure from this high standard towards "simplification for clinical use" is a retrograde step which introduces further variable quantities to be considered in the final clinical evaluation. That the position is not wholly chaotic may be due to the fact that some of these simplifications involve variables which are not independent. Fraser and Rennie[2] have produced evidence which supports such an inference as regards the packed cell volume.

However, in the viscosity we have a simpler physical property of the plasma, and this is almost entirely dependent on a single member of the above complex—the proteins. Miller and Whittington[3] have shown the close correlation between the plasma viscosity and the clinical condition in pulmonary tuberculosis—a correlation which further tests have merely emphasized. Changes in the viscosity mirror the changes in the pathological processes very much more closely than the E.S.R. estimated by even the best technical method.

Whittington[1] has already indicated the complex "periodic" relationship existing between the E.S.R. and the plasma viscosity. Our new results have confirmed this and allowed us to construct two-dimensional charts in which an individual case can be plotted by the simultaneous estimation of the E.S.R. (sextant) and plasma viscosity (chronometer). (We may say that these charts eliminate the problem of the normal with an apparently pathologically high E.S.R., and its opposite—the case with obvious disease and an E.S.R. within the limits ascribed to the normal controls.)

Our results for 650 combined E.S.R. and viscosity measurements show that any simple yet reliable correlation of the E.S.R. with the pathological changes is out of the question. While it is evident from our tests that the E.S.R. (under controlled conditions) measures a definite physical property of the plasma, the variations of this property are so complex that their true interpretation is beyond the scope of present biophysical and biochemical knowledge. Details of these results and of our technique are at present in the press.[4] We hope shortly to publish an abridged version in this country.—We are, etc.,

JOHN HOUSTON.
JOHN HARKNESS.

SIR,—In their letter (Oct. 27, p. 584) D. G. McIntosh and D. M. Keay express opinions about the E.S.R. which will meet with wide agreement. I think, however, that they are too condemnatory. All phthisiologists will be able to recall cases where serial skiagrams remain unchanged with an apparently minimal lesion, negative sputum, and good general condition, and where there is considerable doubt as to activity. In such cases I think that an E.S.R. reading below 10 mm. in 1 hour (original Westergren) is a useful aid to a decision in favour of inactivity. In an institution of this size (450 beds) the number of such cases is not negligible. Serial E.S.R. is also of value if it is either increasing or decreasing in rate, but I entirely agree that the single E.S.R., whether read at 1 hour or 2 hours, is far too inaccurate to be of value.—I am, etc.,

V. COTTON-CORNWALL,
Deputy Medical Superintendent.
Fazakerley Sanatorium, Liverpool.

SIR,—I was much interested in the letter of Drs. D. G. McIntosh and D. M. Keay on the subject of the sedimentation rate, and can agree with them that it is not easy to give definite figures for normal rates.

To take their points serially. The method employed should certainly be stated, though this is of less importance if the rates are not rapid. The column length is the important point, and most methods give similar results for normal cases, as it is the earlier onset of slowing that gives lower rates in the short-tube methods, and this does not occur in the first hour when the rates are slow. When they are rapid, however, it may make a considerable difference.

With regard to the use of citrate or oxalate, it seems of little importance which is used so long as the fact is stated. "Westergren" means "citrate," so no further mention of the anticoagulant used is needed. While citrate certainly does slow the rate slightly, this is of no importance in an empirical test if it is constantly used. Personally, I prefer it, as it is more convenient to use. I may say that I have never known the rate to be slower with oxalate; on the contrary the rate is very constantly more rapid with it. I imagine that it is the slight dilution with citrate solution that causes this.

With regard to the substantial variations in rate stated to have been obtained in normal persons, I should say that there should be the utmost reserve in accepting persons with a rapid rate as normal, and a careful following up should be made before accepting them as such. After all, a physical examination is not infallible (worse luck), and a skiagram is only a shadow.

Concerning the rates in active tuberculosis, it has been observed (Day, *Lancet*, 1943, 2, 99) that a single-hour reading may be normal in convalescent cases, though the second-hour reading may be abnormal, and it was to secure detection of such cases that the sedimentin index was used. On the other hand, I myself have observed normal readings in the first and second hour in one or two cases where tubercle bacilli were actually present in the sputum. One can only imagine that in such cases there was a substantially walled-off cavity communicating with a bronchus. So far as the tubercle bacilli found on gastric lavage are concerned, I would recommend a perusal of a recent article (I am sorry to say I cannot recollect where it appeared) in which a number of acid-fast bacilli found in resting juices were found not to be lethal to guinea-pigs.

No one would venture to claim that any one test in medicine is infallible. We do know, however, that at least a substantial proportion of persons with rapid rates are sick, and the fact is too useful to be ignored. The number of tests I have carried out must now be nearly half-way to six figures, and I (in common with many of my colleagues) have always found it most valuable. With regard to Hilliard's dictum that he had "abandoned the use of the blood sedimentation test long ago," it is unlucky that the phraseology is identical with that of the eminent surgeon at the beginning of the century, with "aseptic surgery" substituted for "the blood sedimentation test."—I am, etc.,

J. W. SHACKLE.
Hayward's Heath.

"The Humane A.P. Refill"

SIR,—I am afraid that I cannot agree with Dr. Alastair Allan's quotation (Nov. 3, p. 607) that "humanity and common sense call for anaesthetization of the needle tract" in giving refills for cases of artificial pneumothorax. I myself held this view until I gave up the use of local anaesthetic, since when I have found that patients invariably prefer their refills without preliminary anaesthetization.

The following technique is found to be most satisfactory. "Local" is used during the induction and until there is an adequate pleural space. This, in the absence of severely restricting adhesions, is generally confirmed by *x*-ray examination during the third week. After that a Morland needle is used. This, with an outside diameter of only 0.9 mm. and a spear-headed point, causes less pain than the raising of an intradermal wheal. The skin and pleura are penetrated with one quick movement, as, naturally, the amount of pain inflicted depends upon the speed of insertion.

I have been most interested in this problem, having several doctors as patients, and, although the idea may sound barbaric, in practice it is remarkably simple and humane. One patient states that, providing the operator is experienced and the needle sharp, it is "absolutely painless," the whole procedure is shorter, and there is no aching around the needle puncture afterwards. The danger of air embolism can also be avoided by leaving the manometer on while giving the refill. This prevents the air being injected under undue pressure, and the swing of the manometer can be observed the whole while, thus making certain that the needle stays in the free pleural space. I do not believe that the danger of pleural shock in an established A.P. is greater when local analgesia is disregarded. However, this is contrary to common teaching, and I shall be grateful to have the views of your readers upon this subject.—I am, etc.,

C. F. HAWKINS,
Medical Superintendent.
Preston Hall, Maidstone.

The Child with Frequent Colds

SIR,—I agree with Dr. G. C. Milner (Nov. 10, p. 667) that the familial incidence of catarrh of the upper respiratory tract is of great interest to general practitioners, but in addition to the environmental chance of infection by atmospheric spread and by a lowered resistance of individuals consuming a similar poor diet, one must also consider the factor of heredity. The inheritance of a narrow nasal passage favouring complete occlusion if engorged must predispose to chronic sinusitis, and it is known that some families are prone to otitis media, presumably due to a particular anatomical pattern of their Eustachian tubes and middle ears.

Age plus duration of infection with the chances of further spread of inflammation and general tissue sensitization to a septic focus explain the varying manifestations of the catarrhal process in members of the same family. For instance, a mother with long-standing tonsillar sepsis and infective arthritis has a young child with antral infection, a poor appetite, and occasional attacks of vomiting, an adolescent child with chronic suppurative otitis media and a chronic laryngitis, while the father and a third child, who "takes after him," escape merely with frequent "colds" because both have a wider formation of the nose.

It should be profitable to conduct a large-scale clinical and bacteriological investigation into these varying manifestations in the small communities of the family.—I am, etc.,

Ilford. R. N. C. SMITH.

SIR,—Like Drs. Mallinson and Milner, I should like to express my appreciation of the careful and painstaking work of Drs. Irwin and Frankel, and my astonishment at the conclusion which they have drawn from utterly inadequate evidence. There are many other possible causes which need to be investigated; they have made a bare mention of a "normal diet" (does "normal" mean "satisfactory" or "usual"?); there is not a word about clothing, not a word about coddling, and not a word about the nervous child. In short:

> "There are more things in heaven and earth, Horatio, than are dreamt of in your hospitals."

The conclusion which I would draw, Sir, is the inadequacy both of materialistic philosophy and of the hospital outlook, and I would plead for the association in these investigations of some members of the profession who can look at these children as individual human beings and not merely as "cases."—I am, etc.,

Wandsworth. F. GRAY.

Surgical Catgut

SIR,—The statement of Mr. John Hosford (Nov. 10, p. 668) that he "has yet to use a British make of catgut which can be relied upon to be consistent in size and strength" is not supported by records of tests made in these laboratories on British-made surgical catgut. It must be admitted that before 1944 the gauging of one manufacturer was often markedly different from that of another. This lack of uniformity, however, is being eliminated by the introduction of new standards for size and strength (*B.P.C.* Additions and Amendments to Part I, 1944, pp. 7–10). Since 1939 there has been improvement in the strength and in the accuracy of gauging of the products of many of the leading British manufacturers. The uniformity attained by them to-day is at least as good as that attained by the American producers. Surgical catgut, however, being a biological product, is not stable for long periods. Under cool conditions of storage it may lose little strength over a period of five years, but samples of the same batch stored at higher temperatures may show considerable deterioration in strength by the end of three years from the date of manufacture.

It must be remembered that the strength and size of surgical catgut are determined in large part during the manufacture of the raw (unsterilized) catgut. British manufacturers of this material export considerable quantities to the U.S.A., where it is processed, packed, and some of it re-imported (before the war) to this country as sterilized catgut. If the British raw product did not satisfy the American manufacturers for its strength and evenness of gauge it is unlikely that they would have continued to purchase it for years before the war and also during the war years.

It would be most unfortunate if the good work done by British manufacturers during the war to keep up supplies of good-quality surgical catgut were to pass unrecognized. The new *B.P.C.* standards introduced only last year may not be the most perfect, but they set out a minimum standard and have been accepted by the manufacturers. It is rare to find material manufactured in 1945 and bought in the open market which on testing fails to comply with these standards.—I am, etc.,

Bernhard Baron Research Laboratories,
Royal College of Surgeons, W.C.2. JOHN BEATTIE.

SIR,—Mr. John Hosford's complaint about the surgical catgut is timely, but it would have had more weight had he been more sure of his facts. Many surgeons have been distressed by the variability of catgut thicknesses, and by the uncertain tensile strength of the specimens which they have had perforce to use in the last few years. The regauging of catgut by the subcommittee of the British Pharmaceutical Codex Revision Committee has made matters much worse, and I have been at some pains to inquire into the circumstances.

It appears that the E.M.S. distribution of surgeons up and down the country brought these men into contact with brands of catgut to which they were unaccustomed. News of their difficulties reached the Ministry of Health, and at the request of their Principal Medical Officer the subcommittee on ligatures and sutures submitted agreed standards for surgical catgut. I am informed that this subcommittee contained no practising surgeon, and that the conclusions reached were opposed to the opinions of the representatives of that catgut manufacturing firm which might well be presumed to know more about the subject than anybody else. The Ministry of Health must be held responsible for the omission of surgical representatives, but it was surely the business of the Royal College of Surgeons to know what was going on and to make its own opinions felt. The surgeon is the consumer of catgut, and had one such had a voice in the proceedings of this committee we should not now be in our present ridiculous position.

In effect the sizes of catgut which were most commonly used —No. 0, No. 1, and No. 2—are now lumped together with No. 2/0 and No. 3, and the whole five sizes are redistributed among three new gradings—No. 2/0, No. 0, and No. 1.

I disagree strongly with Mr. Hosford's opinion that only American catgut was satisfactory before the war. I have used the same brand of English catgut for 12 years and, except for a brief period during the war when the makers' peculiarly thorough methods were impeded by shipping difficulties, I have never had anything but complete satisfaction and reliability until this ridiculous imposition by the subcommittee on ligatures and sutures.—I am, etc.,

Birmingham. FAUSET WELSH.

SIR,—I read with astonishment and regret the misleading and inaccurate letter from Mr. John Hosford (Nov. 10, p. 668). Imported brands of surgical catgut may have enjoyed some popularity before the war, but it is entirely incorrect to assert that this commodity needed or needs to be largely imported. Since 1944 British manufacturers have produced their catgut in sizes conforming with the standards adopted by the *B.P.C.*, which agree with, and allow no greater variation than, the standard American gauges. The uniformity so achieved has proved acceptable to all concerned.

The British suture industry has not only a magnificent war record for high quality and for meeting exceptional demands in circumstances of the greatest difficulty, but is now in a better position than ever before to supply all demands as to type, gauge, strength, etc., that may be made upon it by surgeons in Britain or any other part of the world.—I am, etc.,

ELDRED J. HOLDER,
Chairman,
London, E.C.2. The Sterilized Catgut Manufacturers' Association

Glandular Fever with Neutropenia

SIR,—Having read the description by Lieut.-Col. Gerald Slot and Major F. D. Hart of the appearance of neutropenia in a case of glandular fever (Oct. 13, p. 495) I was surprised to find that in the final paragraph the diagnosis was changed suddenly to infectious mononucleosis. I feel that the use of the term "infectious mononucleosis" in this connexion is undesirable and may lead to confusion; they have not proved that the condition was, in fact, infectious mononucleosis.

Careful examination of the evidence presented by them shows there is much at variance between it and that presented by the majority of other writers when discussing infectious mononucleosis. It is true that Logan[1] stated that sulphonamide administration may suppress antibody formation in glandular fever. The patient in this case was given 30 g. of sulphathiazole —the quantity stated by Price[2] to be that required to produce agranulocytic changes in a susceptible patient. Fitch[3] observes that no less than 33% of patients may show allergic phenomena, although not necessarily to a severe degree, when sulphathiazole is administered. The question, therefore, whether the neutropenia was due to an early agranulocytosis or whether the possibility of an allergic lymphocytosis had been excluded has not been fully dealt with. Stitt, to whom they refer, gives the normal lymphocytic range as 10 to 30%; in this case the levels varied from 42.5 to 78%.

Himsworth[4] raised the point that the factor of mononucleosis *per se* depends on the pathologist's division of mononuclear cells into monocytes and lymphocytes. In order to evaluate more accurately the likelihood of obtaining a positive heterophil agglutination result the number of monocytes per c.mm. is required. He quotes as examples a value of 2,150 monocytes per c.mm. in a case with a positive result, and a value of 520 monocytes per c.mm. in a case with a negative result. Slot and Hart's case had a level varying from 159 to 528 and is thus of a low order. Again, Stitt gives the normal monocyte range as 3 to 8%. In this case the level was almost always not above normal range—3 to 10%. Bernstein[5] believes that in infectious mononucleosis the level of monocytes is at least 60% of the total white count, and that this level tends to be higher in the sporadic as opposed to the epidemic case. When describing an outbreak of infectious mononucleosis in East Africa in the *Journal of Tropical Medicine and Hygiene*[6] a monocyte level of 48 to 80% is given. Further, when describing an outbreak of this condition among a group of young Service patients in an E.M.S. hospital (the group to which Slot and Hart's case belongs) Stevenson and Brown state that 110 out of a total of 123 patients had a high mononucleosis.[7] Halcrow, Owen, and Rodger,[8] discussing eosinophilia in infectious mononucleosis, consider that the level is low at first, rising later. In the patient discussed only one reading was above the normal level of 4%.

With regard to the heterophil agglutination test itself, the authors do not state whether the titre of 1/128 obtained on one occasion was in terms of final dilution or not. Smeall[9] regards a titre of 1/128 as suggestive only. Davidsohn,[10] describing his technique, regards a titre of 1/124 as presumptive evidence only. According to the technique used by Slot and Hart their result should not be worthy of very serious consideration. Even allowing their reading of 1/128 not to be in terms of final dilution, the comparative result would then be 1/320 only.

Again, it is regrettable that no mention is made of the type of non-granular cells seen, whether classified according to Downey[11] or Israëls.[12] In discussing the differential diagnosis of the condition mention should be made of "epidemic cervical adenitis" described by Pruen[13] and Kirkland.[14]

In conclusion, it is regretted that the above criteria were not considered more fully. Infectious mononucleosis is one condition found in the group of glandular fevers, and which has certain definite characteristics; the two terms are by no means synonymous and should not be used in that manner.—I am, etc.,

Breast-feeding to Time-table

SIR,—I have read with interest Dr. J. M. Morgan's letter on infant feeding and duodenal ulcer (Oct. 27, p. 585). We are all aware of the psychogenic factor in this complaint, and no baby who has screamed for half an hour before it receives its dinner at some appointed time can be in a psychological state to digest it when it arrives.

Slavery to time-tables is in my opinion inimical to the whole process of breast-feeding, which largely depends on the mother's placidity of mind. This cannot be maintained unless she is presiding over a contented smoothly running household. How can that be the case if everybody's arrangements have to be turned upside down for the sake of rigid adherence to the infant's schedule ? The baby is an integral part of family life, and his time-table should be planned to fit in with the rest of the family. I shall give two examples. A young husband is due home for his supper at 6.30, but baby must be fed at six. The wife hurries to feed the child and prepare the father's food within half an hour. The result is that he comes home to a scrappy meal, a howling, half-satisfied baby, and an irritable wife. Small wonder that he murmurs, "Oh, Doctor, never again." Yet all this could be avoided if the infant's feed were put forward half an hour or even an hour. Again, the older children want Mummy to take them to the pictures in the afternoon, but no, she can't manage it; baby's feed is due at 2.0 o'clock prompt. They begin to feel that since he arrived Mummy is no longer a companion to them, and the seeds of jealousy are sown.

It is up to us as practitioners to help the nursing mother to arrange her life so that lactation causes the minimum of inconvenience to everyone, including herself. The baby will benefit, for babies are susceptible to atmosphere, and a contented house contains a contented baby. In conclusion, we all realize that the nursing mother requires extra rest and that present conditions of domestic help seldom allow this. Nevertheless, if she can be taught to lie down on her bed and relax completely during the feeds this will afford her a valuable amount of rest which does not interfere with her other activities.—I am, etc.,

Rotherham. ANNE M. TOMS.

Incidence of Breast Abscess

SIR,—Some very startling and challenging figures were given by Dr. A. A. Fulton in the *Journal* of May 19 (p. 693) when he states that 16% of the patients delivered in hospital in a small Scottish town eventually developed a "suppurative mastitis"—i.e., the breast was "spontaneously evacuated or was incised." The figure of 3.5% for district cases of the same type was quoted for contrast. This covered the period of the puerperium and for several weeks later. Dr. Fulton claimed that a true figure could be discovered only by following up the cases for several weeks at the child welfare clinics. His actual hospital figures were as follows:

Total confinements in hospital	748
Number of cases of suppurative mastitis	121 (16·8%)
Number of ditto in 2 weeks after delivery	12 (1·6%)

In another article (*Journal*, Oct. 13, p. 488) he gives the even more startling figure of 25% occurrence of breast abscesses in a series of 250 mothers, and says: "It is to be noted that, with few exceptions, these patients were delivered in hospital."

Redhill County Hospital, Surrey, draws maternity cases from the East Surrey area, including Sanderstead, Purley, and Coulsdon Valley. The general health of the patients is good and the standard of cleanliness is high. As Dr. Fulton reports that the greater number of his cases occurred after discharge from hospital I have made extensive inquiries at the various county clinics (post-natal and child welfare), at voluntary and small local hospitals, and from general practitioners whose patients were delivered in hospital during the period Feb., 1944, to Feb., 1945. About half replied but only three breast abscesses were reported, nor were any patients admitted into this hospital with breast abscesses. The following table sets out the incidence of breast abscesses for some years:

Year	Deliveries in Hospital	Breast Abscesses in Hospital	Occurring After Discharge
1941	780	2 (0·3%)	
1942	960	3 (0·3%)	
1943 to Nov.	760	2 (0·3%)	
1943, Nov. and Dec.	110	6 (5·5%)	
Feb., 1943, to Feb., 1944 ..	890	0	3 (0·3%)
			6 (0·7%)

I regret that Dr. Fulton does not give details of the routine treatment of breasts in hospitals under his care. The following routine is followed at Redhill:

(1) *Ante-natal.*—General cleanliness. The use of spirit, nail-brush, and creams (except in the case of crust formation) is discouraged. (2) *Puerperium.*—Engorgement of the breasts occurs in about 5% of cases, and when this happens 0.5 mg. (only) of stilboestrol is given by mouth. Within a few hours the breast is found to be functioning normally. No massage, hand expression, or hand manipulation is used. In a few cases a second dose of stilboestrol may be required. The nipple is protected by a dressing of ung. "antipeol." Tinct. benzoin. and triple dye, by trapping the infection, are regarded as a real danger and are not used on the wards. Flushed breast is treated with sulphadiazine in sufficient dosage with hot fomentations or antiphlogistine.

In the last two months of 1943 this routine was changed, and in these months an engorged breast was hand-expressed or "milked," also using a breast pump. A period of great worry ensued; there were many cases of non-suppurative mastitis, and six cases of suppurative mastitis occurred in six weeks. I am certain that great damage can be done to the delicate tissue of the breast by massage, even when very gentle, and these traumatic areas flooded with milk form a perfect culture medium for an infection. The mother returns to her home, where she has not time to give meticulous hospital cleanliness to this danger area and so a breast abscess develops. When the practice of the "art of milking or hand expression" was stopped at the beginning of 1944 the abscesses ceased to occur and there were no cases for the year Feb., 1944, to Feb., 1945.

This hand manipulation or milking of the breast is practised in many hospitals. The abolition of the practice might change the frequency of breast abscesses from 25% to a much lower figure.

I have to thank Miss Robinson and her staff of midwives for their co-operation in adhering strictly to the treatment laid down.—I am, etc.,

Redhill, Surrey. PHILLIS DINGLE.

Ergometrine for Migraine

SIR,—In the annotation on ergotamine for migraine (Nov. 10, p. 654) there is no mention of the use of ergometrine in this condition. That this newer alkaloid of ergot also has a beneficial effect in attacks of migraine is scarcely appreciated in this country, and certainly one of our well-known drug houses makes no mention of this therapeutic use in the literature supplied with its product. However, several papers have been published on this subject to which reference is made in *The Pharmacological Basis of Therapeutics* (Goodman and Gilman, 1940). Figures are quoted showing that, whereas 90% of all patients or all attacks are relieved by ergotamine, 37% are relieved by ergometrine, and a further 40% are afforded partial relief.

As ergometrine in the human subject is free from the serious toxic effects that occur from time to time with ergotamine, and as the former drug is effective by mouth in a dose of 0.5 mg. as compared with the need for giving ergotamine by injection, it would seem that ergometrine deserves more attention as a useful and safe therapeutic measure than it has had in the past. In fact, it would really be a wise procedure to give it as routine treatment, reserving the more toxic ergotamine for those cases which do not respond. Further, many people would consider 90% success with ergotamine too high a figure, while from personal experience I would have thought that the ergometrine figures, if anything, erred on the conservative side.—I am, etc.,

Galvanic Stimulation of Denervated Muscle

SIR,—The literature dealing with the place of galvanism in the treatment of muscles denervated as a result of injury to a peripheral nerve shows that such opinions as have been expressed are in the main favourable; as examples, chosen at random, we cite the memorandum published by the Medical Research Council[1] after the last war, and the writings of Pollock and Davies[2] and of Kovacs.[3] What impressed us was the paucity of direct evidence, and it was for this reason that our investigation was undertaken. We hoped to get a clear answer; if it was unfavourable then it was foolish to spend time and money administering a tedious and rather uncomfortable form of treatment; on the other hand, if electrotherapy proved to be of value then it was obviously our duty to give it to as many patients as possible. We agree with Dr. Abercrombie (Nov. 3, p. 622) that "good results may be obtained in the absence of galvanic stimulation," but if galvanism is of value then its effect will be to give excellent results in cases that would otherwise have been only good, and good results in those that would have been mediocre. No one can deny that the results of treatment of peripheral nerve injuries are still too often disappointing.

We share Dr. Abercrombie's regret in our failure to show by direct observation that galvanic stimulation of denervated muscle is of value in promoting recovery from a peripheral nerve lesion. On account of the many variables it was hard enough to find a sufficient number of comparable cases, out of a series of 1,500, for our more limited objective—namely, the demonstration that galvanism does or does not limit muscle atrophy. A full account of the work will be published shortly, and we feel sure that when Dr. Abercrombie has read it he will appreciate some of the difficulties. If functional recovery has also to be taken into account the variables—such as the level of the lesion, the extent of the gap closed by suture, and the time elapsing between injury and operation—become even more numerous; so much so that with the material at our disposal we have as yet found it impossible to demonstrate statistically that recovery was better in the treated cases, though it certainly seemed to be. Thus we fell back on the correlation of experimental and clinical evidence to which Dr. Abercrombie takes exception. Our arguments may have been badly presented, so perhaps it is permissible to restate them briefly, again making reference to a few recent papers which have a direct bearing on the question that we are seeking to answer.

1. Denervated muscle atrophies; the process is a deleterious one, increasingly inimical to good recovery.[4-7]

2. In animals galvanic stimulation retards atrophy and maintains the muscle in a condition closely resembling the normal.[5, 6] The power of a muscle is roughly proportional to its weight; hence, provided that the structure of the muscle is normal or near normal, the greater its weight the better the ultimate function when re-innervation occurs. It is, of course, true, as Dr. Abercrombie says, that one of "the requisites for success in nerve suture is good apposition of the axons."

3. Functional recovery, under the simplified conditions of animal experiment, is better, especially in the early stages, when the muscle is prevented from atrophying[6] (Dr. Abercrombie is incorrect in attributing this work to one of us). Treatment did not produce significant alteration in the actual time of onset of recovery.

4. Since in animals prevention of atrophy is beneficial it is not unreasonable to suppose that it is of value clinically. The question is, Can one arrest atrophy by treatment less rigorous than that usually employed experimentally—treatment to which the average patient can reasonably be expected to submit?

5. The answer is yes.[8, 9]

6. Therefore galvanism, or its equivalent, will have a favourable influence on recovery after a peripheral nerve lesion, provided that the nerve itself has been properly treated.

Dr. Abercrombie suggests that the activity induced by repeated galvanic stimulation may retard regeneration of the nerve, because of the katabolic changes in the stimulated muscle. Has he any evidence to support this alarming statement? If he has, then we shall have to go very carefully, for it may well be that activity in neighbouring normal muscle is equally harmful. In a patient recovering from a partial lesion ought we, perhaps, to prevent activity in the parts of a muscle that are innervated lest that activity should delay re-innervation of the remainder? In the flexor profundus digitorum, which is innervated by the median and ulnar nerves, might activity of the half of the muscle supplied by the intact nerve hinder recovery in the other paralysed half? Experimental evidence does not support this suggestion.[6] Dr. Abercrombie has observed "that the interruption of galvanic treatment has occasionally been followed by an obvious improvement in the rate of recovery"; this is most important, since it may well throw light on an aspect of regeneration of nerves that has not, so far as we know, received consideration. May we suggest that Dr. Abercrombie should publish his evidence, and in the meantime allow us to see the case records on which his observations are based.—We are, etc.,

[9] —— (work to be published shortly).

logical characteristics indicated that it was at least subacute in type. Two weeks later a general enlargement of lymph glands was noted, both liver and spleen were palpable, and a diffuse purpuric eruption appeared. The white cell count rose to 147,000 per c.mm. and the blood lead to 485 microgrammes per 100 c.cm., and death occurred on March 25, 1940.

At necropsy the findings were typical of an advanced leukaemic process with marrow hyperplasia, glandular, splenic, and hepatic enlargement, and histological evidence of leukaemic infiltration of the viscera. This change was most pronounced in the myocardium, liver, and kidneys. In the last, almost the entire renal substance had been destroyed.

Discussion

Although the patient had been exposed to an undue amount of lead for many years, the reason for the development of lead-poisoning was at first uncertain. The onset had been acute after a period of less rather than greater exposure, and after 10 weeks' freedom from further absorption symptoms were very much more severe. During his stay in hospital, on a diet conducive rather to storage than to mobilization of lead, the concentration of lead in the blood rose to 485 microgrammes per 100 c.cm., and death occurred with generalized flaccid paralysis. In this case exposure might have been much in excess of the patient's suspicions, but the progressive rise in blood values appeared to indicate an undue addition to the circulation at a time when storage might have been expected. Some rarefying bone disease was a possible cause, and when the leukaemia developed it seemed probable that the hyperplastic marrow might be responsible for the liberation of lead stored in the trabeculae. The occurrence of trabecular absorption was confirmed at necropsy.

While it is true that the blood changes followed rather than preceded the appearance of poisoning, it is highly probable that marrow changes occurred some time before the blood picture altered. Acute and subacute leukaemia usually show marked marrow hyperplasia with a normal or even subnormal white cell count. Abnormal cells may fail to appear in the circulation for some weeks, and a rise in the count is usually a terminal phase. It is therefore possible that marrow hyperplasia, preceding a blood change, precipitated lead-poisoning by causing trabecular absorption in an individual who had been storing relatively large amounts of the metal in the skeleton over a period of 12 years.

Post-mortem examination of the skeleton for lead by the method of Tompsett (1939) showed abnormally high values for the femur. In Table II these results are compared with values obtained from normal persons by Tompsett and Anderson (1935) and Tompsett (1936).

TABLE II.—*Lead Content in mg. per kg. Fresh Tissue*

	Present Case	Tompsett and Anderson (1935)		Tompsett (1936)	
		Mean	Maximum	Mean	Maximum
Brain ..	0·52	0·50	0·72	—	—
Liver	1·29	1·73	4·63	—	—
Kidney ..	0·66	1·35	3·55	—	—
Vertebra ..	16·40	7·10	14·70	8·40	12·6
Rib	18·40	8·55	12·90	9·75	17·5
Femur ..	293·00	—	—	48·00	108·0

The values for the soft tissues are normal, and the amounts of lead in the ribs and vertebrae are only slightly if at all increased. It is possible that those low values resulted from previous mobilization of lead owing to trabecular absorption. In the final stage of the illness impaired renal function may have contributed to the high blood levels.

When this patient was under observation the possibility of lead-poisoning due to mobilization of the metal in this manner had not been considered. The chance of investigating another such patient was so remote that some other approach to the problem had to be sought. Accordingly an investigation of blood-lead levels was undertaken in individuals exposed to a domestic lead hazard and suffering from rarefying processes affecting the skeleton (Brown, 1946). This investigation has revealed that, even without undue exposure to lead, osteolytic processes may result in high blood-lead concentration. It is to be expected, therefore, that where exposure has been excessive rarefying lesions in bone may result in lead-poisoning.

Summary

The case has been described of a compositor in whom lead-poisoning was caused by mobilization of lead from the bones by leukaemic marrow hyperplasia.

Lead-poisoning in a lead-worker may not indicate immediate exogenous lead intoxication.

Marrow hyperplasia in a lead-worker may precipitate lead-poisoning.

Anaemia in a lead-worker may be the cause, and not the result, of lead-poisoning.

We are indebted to Dr. David Smith for permission to study the patient in his care, and to Dr. A. B. Anderson for helpful criticism and advice.

A CASE OF CHRONIC UNDERMINING ULCERATION TREATED WITH PENICILLIN

BY

AUBREY LEACOCK, F.R.C.S.

Assistant Surgeon, E.M.S.; Chief Assistant to a Surgical Unit, St. Bartholomew's Hospital

While the American literature contains many descriptions of this type of ulceration, no papers on the subject could be found in the English medical press. Though rare, the condition deserves wider recognition.

Case History

A soldier in the Pioneer Corps, aged 32, while serving in North Africa was given an injection of T.A.B. in the left upper arm on Oct. 23, 1943. Four days later his arm rapidly became very painful, red, and swollen, and his temperature rose to 103°. A diagnosis of cellulitis was made, and he was treated with chemotherapy and fomentations. On Nov. 7 his arm was incised and much pus evacuated, relieving his pain. An aerobic haemolytic streptococcus was grown from the pus. The incision continued to discharge freely, but the infection spread subcutaneously, producing a large pocket of pus, which was opened more widely on Dec. 10, and again on Jan. 19 and Feb. 29, 1944. During this time the arm became more painful, especially around the edges of the inflammatory process, which gradually but inexorably spread down to the elbow.

By April 3, when he had been evacuated to England, there was a large ulcer 8 in. by 3 in., extending from the deltoid region to the back of the elbow. There was moderate pain in the region of the ulcer and the whole area was extremely tender. The temperature varied, rising to 100°, and the pulse rate was slightly raised. The base of the ulcer consisted of pale unhealthy granulations, and most of the edge was undermined, with up to an inch of overhang. In a few places the edge was adherent to the floor of the ulcer and its appearance suggested that epithelization was beginning. The undermined edge was bluish, shading outwards into a slightly raised red area, outside which was normal skin. There was no zone of cutaneous gangrene. In the floor of the ulcer were two sinuses about 1½ in. deep. The humerus showed mild periostitis. There was no lymphadenitis.

In the differential diagnosis, syphilitic, tuberculous, diphtheritic, and amoebic ulceration were considered, but no evidence of any of these diseases could be found.

On April 28, at Friern Hospital, the edges of the ulcer were excised with a knife, and the sinuses opened up to give a flat surface. A gauze dressing was applied and the limb immobilized in a plaster spica. The plaster was left on for a month, during which time there was little pain from the ulcer and the patient's general condition improved, but when the plaster was removed the ulcer had extended downwards to just beyond the point of the elbow, though lateral spread had stopped. A biopsy of the active edge showed non-specific inflammatory changes extending outwards beneath the intact epidermis. Numerous Gram-positive diplococci and occasional Gram-positive bacilli were seen in the floor of the ulcer.

Next, a great variety of antiseptic and bacteriostatic dressings were tried, including sulphanilamide powder and proflavine powder as well as more old-fashioned remedies, but none produced any significant improvement. Zinc peroxide could not be obtained.

On June 6 a swab from the edge of the ulcer gave a profuse growth of an aerobic haemolytic streptococcus, with moderate numbers of *Staphylococcus aureus* and *Pseudomonas pyocyanea*. The first two organisms were sensitive to penicillin *in vitro*, and on

Anaesthetic Risks

SIR,—Let me admit at once that I know of no proof in the scientific acceptance of the term that there is a "greater or lesser degree" of damage to the brain cells when their oxygen requirements are fully met. But man does not live by bread alone. We do many things successfully for which as yet there is no scientific proof. Assuming that we may class chloroform, ether, and alcohol together as narcotics—and they are usually so classed—then there are a number of facts which suggest that it is unlikely that a patient can be deeply anaesthetized without some trace of the action of the anaesthetic being left on his brain cells. T. S. Clouston says: "The injurious effects on the brain structure and functions of a steady habit of taking too much alcohol extending over years is admitted by every physician and can be proved microscopically by any good modern pathologist." William MacDougall found, in a series of experiments demanding his attention and the use of his muscles in co-ordination therewith, that after 1 oz. of whisky he made 11% more errors and after 3 oz. 54% more errors than when they were conducted without. Ralph M. Waters, one of America's leading anaesthetists and advocate of cyclopropane, says: "I have come gradually to realize two facts: the first that relief from pain is purchased always at a price, and the second that the price in both morbidity and mortality does not greatly differ whatever the agent or agents used." All this is in accordance with one's experience in life and was put long ago in the phrase: "Whatsoever a man sows that shall he also reap."

If, then, it can be proved by any good pathologist that repeated doses of alcohol have injurious effects on the function and structure of the brain, when do they begin? Can we suppose that the brain takes no notice of the first hundred thousand and then suddenly starts to register? It would be more reasonable to suppose that each dose, even the first—and anaesthesia to the point of muscular relaxation is a good first dose—leaves its mark. We are in the habit of regarding functional disturbance as due to a reversible organic change; it may be that this explanation is merely a euphemistic expression for the lack of sufficiently delicate instruments to record slight changes, or of powers of observation. Think of the thousands of times skilled professors of bacteriology looked at mouldy cultures without spotting the effect of moulds on bacterial growth. It is probable that all anaesthetics, even local or spinal, have some deleterious effects; but in the hierarchy of nerve cells those of the brain are the highest: why damage them when there are alternative methods?

One more point. Dr. A. C. Douglas (Oct. 27, p. 583) uses the words "when the oxygen requirements are fully met." How do we know that they are? Anaesthesia is generally supposed to be due to a process of suboxidation. The haemoglobin may be 100% oxyhaemoglobin, but such evidence as is available suggests that the anaesthetic, like Horatius, holds the bridge between the outside of the cell and the inside. This action is indeed the *sine qua non* of anaesthesia.—I am, etc.,

E. FALKNER HILL.

Epidemic Diarrhoea and Vomiting

SIR,—May I add a few words to the most interesting article by Drs. Brown, Crawford, and Stent (Oct. 20, p. 524). I was struck by an identical outbreak of epidemic diarrhoea and vomiting in Mansfield between May and August, 1945. I had the opportunity of treating several scores of cases, which did not differ in their clinical picture from those described by the three authors.

What puzzled me most was the fact that all those cases concerned panel and other working-class patients only. I failed to notice any similar case in any of my well-to-do family patients. My first impression was that the disease could have been related to the excessive consumption of ice-cream or fish-and-chips. Further interrogation of successive patients did not reveal any proof for this assumption, however. The duration of the cases observed by me varied between a few days and a couple of weeks, and here again I think it was the general standard of life as well as personal cleanliness of the family which was the determining factor.

As for treatment, I would like to stress that I refrained from ordering any laxatives or sulphaguanidine. I found that a 24-hours fast (except ample intake of soda-water, barley-water, or cocoa made with water and saccharine together with mist. kaolin. ℥ss t.d.s.) followed by a two-days diet of milk, milk puddings, and dry toast, gave very satisfactory results.—I am, etc.,

Mansfield, Notts. D. LAUTERBACH.

Acroparaesthesia

SIR,—In an article on acroparaesthesia Dr. F. M. R. Walshe says (Nov. 3, p. 596), with reference to its causation, that "the fact provides a clue that no one is interested to follow to its logical conclusion—namely, that it suggests a mechanical origin of the syndrome." Ten years ago in *The Osteopathic Lesion* (Heinemann), on pages 81, 84, and 85, I and W. Hargrave-Wilson drew attention to the fact that this condition was probably of mechanical origin and differentiated it from Raynaud's disease. The most likely mechanical lesion is that of acute or chronic joint strain (osteopathic lesion) of one or more of the joints of the upper dorsal or lower cervical vertebrae. The joint lesion causes the soft tissues in the area to be congested and held in tension. The symptoms are probably caused by pressure or the initiation of a somatico-arterial reflex.

Dr. Walshe further states that "when the desperate patient has sought relief from practitioners not on the *Medical Register* 'manipulation of the spine' has still further added to her torments," and that complete rest is essential in treatment. My experience with manipulation for over twenty years is quite the contrary. There are, unfortunately, without doubt many individuals practising manipulation who have no qualifications for the title of osteopath, and in whose hands results such as Dr. Walshe mentions are to be expected.

While highly satisfactory results are obtained by osteopathic manipulation without complete rest, it is important to impress on the patient that the cause is mechanical, and that repeated strain to the neck and upper dorsal must be avoided. The common causes of strain, apart from direct trauma, are lifting and carrying, prolonged writing, sewing, knitting, car driving, etc. The reason for the increase in incidence in recent years is obvious. Complete rest will naturally relieve the symptoms, but if the condition is mechanical, as Dr. Walshe agrees it probably is, the symptoms will sooner or later return unless the underlying mechanical abnormality is corrected.—I am, etc.,

London, W.1. GEORGE MACDONALD.

Potassium Thiocyanate in Hypertension

SIR,—The reference by Dr. T. Izod Bennett (Nov. 10, p. 661) to potassium thiocyanate as being of benefit in hypertension is of interest, and he may like to know that as a result of examining a large number of lead workers, in whom hypertension is so often found, my experience is that this salt, which is common in normal saliva, diminishes and tends to disappear from the saliva of those men who give evidence of lead poisoning.—I am, etc.,

Swansea. G. ARBOUR STEPHENS.

Phytic Acid and Calcium Deficiency

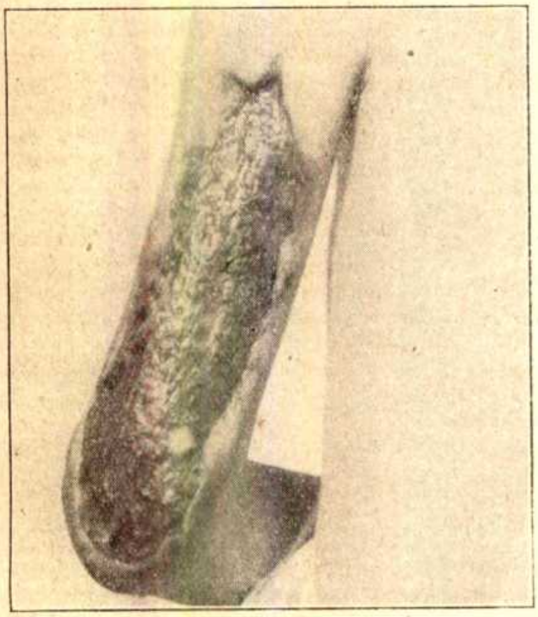
SIR,—I should like to rectify the impression given by your annotation. The facts are as follows: If a subject is given first white bread and afterwards brown bread the calcium balance becomes negative in the latter. This has nothing to do with phytic acid at all, as we have shown (Harris and Vernon, *J. Physiol.*, 1943, **102,** *Proc.*, Oct. 2). If a subject is in the habit of eating the brown fortified loaf, and he is afterwards given brown bread of the same extraction but without the added calcium, there is no negative calcium balance. Here are the actual figures which we have obtained from a subject after eating brown bread to which calcium was not added. Calcium intake 0.737 g., calcium output in urine 0.172, in faeces 0.565 g.; in urine and faeces 0.737. Output 100% of the intake.

It is clear that if phytic acid were the cause of the negative calcium balance, and the added calcium were to prevent this negative balance, the eating of brown bread without the added calcium should have produced a negative balance, which it did not. This in itself shows conclusively that the whole phytic acid theory is only a figment of the imagination. You say in

June 12 local penicillin treatment was begun, using a solution containing 100 units per c.cm. Rubber tubes were introduced into the sinuses and along the most undermined and painful parts of the edge, and penicillin injected through the tubes to keep the dressing wet.

After 24 hours of penicillin treatment a swab grew only a few streptococci, and after 48 hours all penicillin-sensitive organisms had disappeared. After five days the appearance of the ulcer had enormously improved; there was no pain, little tenderness, and epithelization had begun. Infection with *Ps. pyocyanea* persisted, but seemed to be diminished by 1% acetic acid dressings.

Epithelization progressed rapidly from the edges and from two islands of epithelium which appeared in the floor of the ulcer. In addition the size of the ulcer diminished considerably, owing to contraction of its fibrous base. The sinuses did not heal until early September, and at that time epithelization stopped. The remaining skin defect, about 3½ in. by 2½ in., was covered by a Thiersch graft, which was 80% successful. Healing was complete by Nov. 7, and on Jan. 15, 1945, the patient was discharged, with a stable scar and a good range of elbow movement. The only residual disability was some weakness of the triceps.



Chronic undermining ulcer of arm.

Discussion

Spreading, undermining, burrowing infections of this kind have been described at length by Meleney and his colleagues (1935, 1937, 1939) and by other American surgeons (Pennoyer, 1937; Rhoads, 1937). Dermatologists have described in the American and French press an apparently identical condition, under the name of phagedaenic ulcer or phagedaena geometrica. Greenbaum (1941) gives a full review of the dermatological papers on this subject.

Meleney has found constantly associated with these lesions a haemolytic streptococcus which is a facultative aerobe, but which, when obtained from the undermined edge of the ulcer or from the depths of the sinuses, grows best under anaerobic conditions, and grows in pure culture. Meleney therefore classifies it as a micro-aerophilic organism, and believes that it is an aerobic streptococcus which becomes adapted to thrive in anaerobic or micro-aerobic conditions, as in the depths of sinuses or under overhanging skin edges. *Staphylococcus aureus* was also found in most of the recorded cases.

The process may start as an infection of a surgical incision or of a traumatic wound, or as a lymphadenitis, and at first resembles an ordinary cellulitis or adenitis; but suppuration, instead of becoming localized, progresses. On the trunk and limbs the process spreads mainly beneath the skin, producing the typical ulcer with undermined edges; while in the axilla, perineum, or groin the infection also burrows deeply, producing extensive sinuses. Daughter ulcers may appear, with undermined skin bridges separating them from the main ulcer. The infection slowly progresses over months or even years, and amyloid disease may develop, or death may follow the erosion of deep vessels.

To be distinguished from this type of ulceration is the well-recognized condition chronic progressive post-operative cutaneous gangrene, which has been described, under a variety of equally clumsy names, by numerous authors, including Brewer and Meleney (1926), Nightingale and Bowden (1934–5), Stewart-Wallace (1934–5), and Willard (1936). After operations for infective processes in the chest or abdomen a chronic spreading infection may develop in the region of the wound, commonly starting round a tension suture, and spreading in two to six weeks to produce a large ulcer 6 in. or more in diameter. The advancing edge shows a peripheral red or purple zone and a raised irregular margin, inside which is a wide or narrow zone of gangrenous skin. The muscles are unaffected. A non-haemolytic streptococcus is found in pure culture in the advancing edge, and this organism grows best under anaerobic conditions, though aerobic growth also occurs. *Staphylococcus aureus* is found in the gangrenous zone, and the process is regarded as a symbiotic infection.

The case described, although the organism always grew readily under aerobic conditions, appears to belong to Meleney's group of chronic undermining ulcers.

Treatment

Meleney has obtained good results by treating these chronic undermining ulcers with a suspension of zinc peroxide in water. This liberates oxygen in an active form over a period of several hours. It was found that, unfortunately, only one of the commercial manufacturers of zinc peroxide (the Du Pont Company) could provide a material which gave consistently satisfactory results (Meleney and Johnson, 1937). The suspension was used as a wet dressing and introduced into the depths of the lesion by rubber catheters. Incisions and trimming of edges were often necessary to permit the peroxide to reach the area of active spread.

The only successful recorded treatment of progressive post-operative cutaneous gangrene is wide excision of the advancing edge with knife or cautery. This has been successful whether or not zinc peroxide was subsequently used.

In the case described above the response to penicillin was much more rapid than could have been expected from the use of zinc peroxide, and suggests that local penicillin may become the treatment of choice for this rare condition.

Summary

A case of chronic undermining ulceration is described. The condition responded dramatically to local penicillin treatment. The aetiology of the condition is discussed, and it is distinguished from chronic progressive post-operative cutaneous gangrene.

I would like to thank Mr. Reginald Vick for permission to publish this case.

Wartime nurses with good nursing experience who satisfy certain conditions will, if they decide to make nursing their peacetime career, be allowed six months' remission in their training for State Registration. This concession, agreed to in principle by the General Nursing Councils for England and Wales and for Scotland, will apply to all those who have had suitable nursing experience in the Forces, or as nursing auxiliary members of the Civil Nursing Reserve, British Red Cross Society, the St. John Ambulance Brigade, or the St. Andrew's Ambulance Association. Formal rules to give effect to the scheme are being prepared by the two General Nursing Councils for submission to Mr. Aneurin Bevan, Minister of Health, and Mr. Joseph Westwood, Secretary of State for Scotland. But meanwhile the two Ministers, in view of the urgency of attracting recruits to nursing, have written to the authorities concerned asking them to bring the scheme to the notice of all who may qualify for the concession.

your annotation that the phytic acid is lost by baking. If this is so, why then was the calcium added to brown bread? and why has Widdowson, the co-worker of McCance, stated recently in the *British Medical Bulletin* that the reason why rickets is prevalent in Dublin is because of the whole-meal bread?—I am, etc.,

I. HARRIS.

The Discovery of X Rays

SIR,—In your editorial on the discovery of *x* rays (Nov. 3, p. 608) you state: "The *Lancet* (Jan. 11, 1896) was the first medical journal in this country to comment on Röntgen's discovery, and in its leading article the wit of Mr. Samuel Weller was invoked to pour a cold douche upon the supposed possibilities.... Meanwhile the *British Medical Journal* (Jan. 18, 1896) came out with a carefully considered and laudatory article by Prof. Schuster, of Manchester, and assessed the new discovery at its proper medical valuation. From that date onwards all journals contained numerous articles on *x* rays and their applications."

May we point out that your first statement is incorrect. In the *Medical Press and Circular* of Jan. 8, 1896, under the heading "Electrical Photography in Surgery," there is the following note:

> "The news of a remarkable discovery in photography is reported from Vienna. Briefly it consists in the discovery of a new conductor of light. Professor Röntgen, the well-known professor of the Würzburg University, has succeeded in photographing metal weights shut up in a wooden box, without showing anything of the casing on his negative. He is also said to have photographed the bones of the hand, all the soft parts being invisible. He photographs by means of light of an exhausted Crooke's pipe, through which an inductive current is passed. The discovery appears to be so far that the rays in question penetrate wood and flesh, but not bone or metal. It is surmised that photographs of the kind mentioned may have a valuable practical application in the discovery and location both of fractures and of bullets. If this discovery be sustained it will certainly take a first place among the many marvels of this scientific age. Those of our readers who are versed in electrical research may have already heard of Professor Röntgen's interesting researches."

Priority, therefore, not merely in comment but in correct appraisal, belongs to the *Medical Press and Circular*, and may we add that the then editor, Dr. David Walsh, gathered together a group of enthusiasts who met in the offices of this journal in King William Street, Strand, at which meeting the Röntgen Society was founded with Prof. Silvanus Thompson as president, and the editor as honorary secretary. Furthermore, the editor's book on the subject, *The Röntgen Ray in Medical Work*, published by Baillière, Tindall and Cox, was, we believe, the first book in the world on this subject.

In the interests of historical accuracy we hope you will find room for this correction.—We are, etc.,

CECIL P. G. WAKELEY.
London, W.C.2. G. E. BREEN.

The annual report of the Medical Officer of Health for Liverpool (Dr. W. M. Frazer) tells the same story as that of the other large towns, indicating a very satisfactory position from the point of view of vital and epidemiological statistics in the sixth year of the war. The infant mortality of 57 to 1,000 births is much the lowest recorded in the city, comparing with a rate of 81 in 1943. The rate has fallen to little more than a quarter of the level at which it stood at the beginning of the present century. The number of deaths from infective diseases, not including diarrhoea and influenza, was 0.3 to the thousand of population. This low rate is attributed to two factors—first, the great reduction in the number of cases of diphtheria, the result of the extensive campaign for diphtheria inoculation carried out during the last two years; and, secondly, the almost complete absence of typhoid fever, which was responsible for only one death in 1944. The figures for pulmonary and non-pulmonary tuberculosis indicate a return towards the lower rates obtaining before the war. (The death rates for pulmonary tuberculosis during the years 1936–9 ranged from 0.81 to 0.85 to the thousand, and in 1944 the figure was 0.9.) During the war an increase of early syphilis in both sexes, but most strikingly in the female population, has been noted. In males the number of cases in 1944 was 417 and in females 278, comparing with 187 and 25 respectively in 1939. An intensive effort has been made in Liverpool to encourage cow-keepers to supply cleaner milk.

Obituary

T. SAXTY GOOD, O.B.E., M.R.C.S.

By the death of Thomas Saxty Good the profession has lost one of the pioneers of modern psychiatry, and Oxford medicine in particular a beloved and honoured colleague. Not least will he be mourned by his many patients, to whom he gave so much comfort and skilful guidance.

Good belonged to a medical family; his father, J. Saxty Good, who died at an early age, was a dentist, and Thomas was the ninth member of his house to be educated at St. George's Hospital. He qualified at the early age of 22, and after holding various house appointments joined the Littlemore Asylum as medical officer. This proved to be his home for the next forty years, as after eleven he succeeded Dr. Sankey as medical superintendent. During the 1914–18 war the asylum, afterwards known as the Ashhurst Mental Hospital, was converted into a hospital for shell-shock cases, etc., under his command. Besides this important work Lieut.-Col. Good, as he then was, acted as consulting psychiatrist to the 3rd Southern General Hospital, was chairman of the recruiting board, and, while looking after the welfare of their patients, did all he could to protect the interests of his absent colleagues. In recognition of his work he was awarded the O.B.E. (Military) in 1919. Early in 1918 he started a clinic for nervous disorders at the Radcliffe Infirmary—one of the pioneer out-patient clinics of its kind. A few years later the University of Oxford gave him an honorary degree and appointed him university lecturer in psychiatry and nervous disorders. In 1931 Good was president of the Royal Medico-Psychological Association. When the B.M.A. met at Oxford in 1936 he was president of the Section of Neurology and Psychological Medicine, and he was a member of the B.M.A. Committee on Mental Health in 1938–40. In the City of Oxford he co-ordinated the work connected with the care of mental defectives, and was active in instituting with the Education Committee a clinic for child guidance, and afterwards for many years served as a member of the Child Guidance Council and committee of the Institute for Scientific Treatment of Delinquency.

Good was very humane in the treatment of his patients, allowing them out on parole and keeping the wards unlocked; and despite the initial misgivings of others he was certainly justified by results. Though he was a man of many interests, a welcome and entertaining companion, a good sportsman with both gun and rod, and a really talented artist in wood carving, Good never completely retired. During the last war especially his experience and knowledge made him a valued member of medical boards, and he gave his services to the hospital as an assistant where he had formerly been in charge. The loss of his companionship, humour, and unstinted help will be felt by all his contemporaries. E. M.

DOUGLAS ARTHUR CROW, M.B., Ch.B.

Mr. Douglas Crow, ear-nose-and-throat surgeon to the Royal Sussex County Hospital, Brighton, whose untimely death on Nov. 3 has distressed his colleagues, friends, and patients, was a striking figure and a brilliant and unusual personality—surgeon, artist, craftsman, philosopher, and archaeologist. His most notable quality was his intransigent integrity, which sometimes led his mind into queer bypaths and made some people find him "difficult"; but his every action was illuminated by an uncompromising honesty of purpose. As a craftsman "Tim" Crow was supreme, whether as surgeon and bronchoscopist or in the various arts which he practised. His surgical technique was confident, gentle, swift but unhurried; his opinion was founded on wide experience and reading, and as a consultant he was always reliable and helpful, if opinionated; he had never taken any higher surgical qualifications, and saw no particular reason why he should, for his training had been thorough and prolonged. He illustrated his own articles and books, being particularly fond of coloured chalk drawings, and he made and carved his own dining-room furniture as well as other admirable examples of cabinet-making. When he published, in 1942, a rather depressing novel, *Unwitting Crowd*—though it had some passages of rare beauty—he did it in his own way: he printed it himself, drew and made the blocks for the illustrations, bound it himself in leather, and presented it to a few chosen

Medical Memoranda

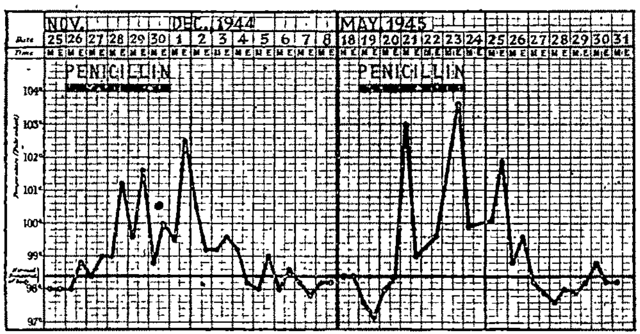
Reaction to Penicillin

Toxic reactions in man reported so far from the use of penicillin have been few and insignificant compared with its high therapeutic activity. In a survey of penicillin therapy, just published in the U.S.A. by John A. Kolmer, the toxic reactions consisted chiefly of fever, headache, skin eruptions, tingling in the testes, thrombophlebitis, and pain at the site of injection. Some Herxheimer reactions have occurred in the treatment of syphilis. The incidence of many of these reactions has dropped considerably, however, owing to better methods of purification; furthermore all penicillin issued is pyrogen-free. There appears to be no appreciable difference between the calcium and sodium salts. Fever, it has been suggested, may be due to bacterial toxins following the antibacterial effects of penicillin. Acute polyarthritis has apparently not yet been described, and the following case, in which it occurred after intramuscular penicillin administration for an infected compound fracture of the leg, may be of interest.

CASE HISTORY

Mr. A., aged 45, an electrician, was admitted to hospital on Nov. 5, 1944, with a compound comminuted fracture of the tibia at the junction of upper and middle thirds, and of the fibula just below the neck. The wound was excised under general anaesthesia and the leg encased in plaster-of-Paris. The patient remained afebrile, but the wound became infected and he complained of throbbing pain at the site of fracture. A culture from the wound showed *Staph. aureus* and haemolytic streptococci, both penicillin-sensitive. An intramuscular penicillin drip was started on Nov. 26—100,000 units daily for five days. The temperature rose sharply to 102.4° and the patient complained of malaise and generalized joint pains. Penicillin was discontinued on the 29th, and two days later the temperature fell to 99°, returning to normal after three days. The joint symptoms disappeared.

The patient was eventually discharged on April 7, 1945, with the limb encased in plaster-of-Paris. He was readmitted a month later with a secondarily infected plaster dermatitis, the culture showing penicillin-sensitive *Staph. aureus*. He was afebrile. Penicillin was administered by intramuscular injection, 20,000 units three-hourly. His temperature rose to 103° and joint pains started 24 hours later.



The joints affected were the right temporal, the neck, both shoulders, right elbow, left wrist, and left knee. These joints showed no swelling or fluid, but were painful on movement. He gave a history of having had rheumatic fever at the age of 11 and lumbago a few years ago. On examination his throat was clean and culture negative, and no abnormal physical signs were found in his cardiovascular system. Blood examination showed a slight polymorphonuclear leucocytosis, and his sedimentation rate was 40 mm. in one hour. Sodium salicylate 15 gr. was given two-hourly, but was discontinued after 48 hours as there was no improvement. The penicillin was stopped after three days, when his temperature fell to 99°, returning to normal after two days. The joint pains subsided several days later, his skin condition improved, and he was eventually discharged.

This case is published by permission of the Medical Superintendent and Mr. F. D. W. Collier, F.R.A.C.S.

Paddington L.C.C. Hospital. H. JASLOWITZ, M.R.C.S., L.R.C.P.

S. Cundel, M. C. Wheelock, and G. J. Grimaldi (*U.S. nav. med. Bull.*, 1945, **45**, 97) state that mumps and mumps orchitis are still urgent naval and military problems. Atrophy of the testes was found in 55% of the cases of orchitis. Epididymitis is frequently associated with the orchitis of mumps. Pooled plasma (160 c.cm.) given intravenously to mumps patients as a prophylactic does not lower the incidence of orchitis.

Reviews

PHYSICAL ASPECTS OF RADIUM THERAPY

Radium Therapy. Its Physical Aspects. By C. W. Wilson, M.Sc., Ph.D., F.Inst.P. (Pp. 224; illustrated. 18s.) London: Chapman and Hall. 1945.

The author has written a book about the place of physics in radium treatment. Though not quite clear of the empiricism with which it started, this treatment is gradually shaking itself free and taking on a quantitative garb; but this can be so only from the physical aspect. No one looking at the problem of how to treat malignant disease is likely to be deceived very long by the idea that since physics is an exact science its application to radium treatment will also render this an exact process; the body remains an inscrutable variable. None the less it is a good plan to be as exact as possible in those parts of the subject that allow it. This is not a book about the actual treatment of cancer, as the title may suggest to some readers, but about the particular kind of physics that can render service when the particular kind of radium treatment has been decided on medical grounds. The subject is a comparatively young one, yet there are now established modes of treatment (superficial, interstitial, intracavitary, and so on) which can reasonably be duplicated by centres all over the world. In each case the author has the relevant physics of the method to put before the reader; the book is well written, and illustrated with good line drawings and excellent photographs.

VASCULAR SCLEROSIS

Vascular Sclerosis. With Special Reference to Arteriosclerosis, Pathology, Pathogenesis, Etiology, Diagnosis, Prognosis, Treatment. By Eli Moschowitz, M.D. Oxford Medical Publications. (Pp. 178; illustrated. 20s.) New York Branch of the Oxford University Press.

This book by Dr. Eli Moschowitz is a useful monograph on a somewhat complicated subject which the author has endeavoured to approach from the standpoints of a clinician and of a pathologist. His aim throughout has been to take a wide view, so it will be found that he brings in sclerosis of all the vascular system—not only the arteries but also the veins and capillaries and even the lining of the chambers of the heart. Naturally, it is not possible to give in a book of this size a very exhaustive treatise on all the available information on such a wide subject, but it is valuable to have ideas put forward clearly which are based on changes found in the vascular system as a whole. In these attempts the author has met with a considerable degree of success. He believes that the structural changes in the vessels, which are irreversible and progressive, consist of hyperplasia as a primary reaction, followed by deposits of lipoids, hyalin, and calcium, which all lead to enlargement, deformity, and loss of elasticity. He concludes that arteriosclerosis is largely the result of the interaction of two factors, both of which may vary; one is intravascular pressure and the other is time. The factor of intravascular pressure leads him into a fairly full discussion on hypertension and its relation to arteriosclerosis; not only to primary or essential hypertension, but to any increase of pressure above the normal, such as may occur in the pulmonary circulation; and from that he discusses the causes of essential hypertension itself. Among these he puts psychological conditions first; second he puts Graves's syndrome, perhaps attributing more to it than is usually done in this country.

There are short chapters on sclerosis of the veins and the capillaries, on experimental arteriosclerosis, and on the relation of arterial disease to diabetes. Finally there is a chapter on therapy. Dr. Moschowitz is sceptical about the permanent benefit of even the most extensive degree of sympathectomy, though he admits that the operation is still in the experimental stage and that a great deal of further information on after-effects is required. There are good illustrations, particularly the photomicrographs, and the book can be recommended to anyone who is looking for a sensible discussion on a complex subject, approached from a wide point of view.

friends. At one time archaeology was, after surgery, his chief pursuit, and he walked fast and hatless along the green roads of the Downs, dug with Dr. Curwen in prehistoric hill-forts, and filled his house with pieces of ancient pottery. He was an early and keenly interested visitor to Soviet Russia, though his first enthusiasm waned. He had considerable knowledge and appreciation of Chinese art, and his presidential address to the Brighton and Sussex Medico-Chirurgical Society in 1938, entitled "A Blind Man with a Lantern" (afterwards printed in pamphlet form), was a study of the Chinese philosophy of life, which appealed to his own fastidious outlook. He had served in the war of 1914–18 as a captain, R.A.M.C., though he never spoke of it, and in 1938 he circulated a pamphlet entitled "The Pacifist Faith of a Surgeon," for he had learned to hate all war, and 1939 depressed him deeply.

Douglas Crow, born in 1889 at Loughborough, was educated at Fort William and Edinburgh University, where he had a distinguished career, winning several prizes and qualifying in 1911. He became house-surgeon at Doncaster Royal Infirmary and at the Sussex Throat and Ear Hospital, Brighton, and went into general practice at Brighton, though keeping up a connexion with the Throat and Ear Hospital. The late Mr. Arthur Hutchison of Brighton encouraged him to specialize in otolaryngology, and after having served as registrar to the Central London Throat, Nose, and Ear Hospital and having been one of the first Englishmen to attend Chevalier Jackson's course in bronchoscopy at Philadelphia, he was appointed honorary surgeon to the Sussex Throat and Ear Hospital in 1920 and to the Royal Sussex County Hospital in 1925. In 1927 he published a book on *The Ear, Nose and Throat in General Practice*, a particularly stimulating and well-illustrated production, not a formal textbook but a vigorous expression of personal opinions, with emphasis on principles. In 1930 he opened a discussion on bronchoscopy and oesophagoscopy in the Section of Laryngology of the Royal Society of Medicine, characteristically beginning with an account of his one (and only) failure; he frequently reported cases of interest at meetings of the Sections of Laryngology and of Otology and in the medical journals, including this *Journal*. He had a large consulting practice extending all over Sussex, held appointments as consulting surgeon to Haywards Heath Hospital, the Royal Alexandra Hospital for Sick Children, Brighton, and the Brighton Infirmary, and will be greatly missed.

Dr. Frederic Ryott Percival Taylor, for many years medical superintendent of the East Sussex County Mental Hospital, Hellingley, died at Eastbourne on Oct. 5. He was born in Berkshire, near Newbury, on March 2, 1865, and from the local grammar school went with an entrance scholarship to Westminster Hospital, where, after qualifying M.R.C.S., L.R.C.P. in 1889, he was house-surgeon. He graduated M.B., B.S. in 1891, and took his M.D. after serving as resident medical officer at Queen Charlotte's Hospital. Dr. Taylor's long experience of mental defect and disorder began as assistant medical officer at the Earlswood Asylum, and at the L.C.C. Mental Hospital, Claybury. He was then medical superintendent of the Darenth Home for Mental Defectives, and in 1902 became resident physician and medical superintendent at Hellingley Mental Hospital. In 1922 he was appointed physician for nervous disorders at the Princess Alice Memorial Hospital, Eastbourne, and neurologist to the Ministry of Pensions for the Brighton area. He joined the B.M.A. in 1891, and held office as vice-president of the Section of Neurology and Psychological Medicine at the Eastbourne Annual Meeting in 1931. The funeral service was held at Hellingley Hospital Chapel on Oct. 11.

The sudden death from cerebral haemorrhage at the early age of 47 of Dr. R. P. S. **Lewer**, of Knayton, Thirsk, on Oct. 20, cast a gloom over the area. He was a native of Dorset, and son of the late Dr. Edward Stewart, of Burnley-in-Wharfdale. He was a grandson of General Robert Lewer, Director of Medical Services at Gibraltar, and great-great-grandson of the Rt. Hon. Charles Kendal Bushe, Lord Chief Justice of Ireland and Master of the Queen's Bench. Educated at King's School, Canterbury, Dr. Lewer served in the war of 1914–18, later qualifying in Dublin L.R.C.P.&S.I., L.M. He practised for the past six years at Knayton in Yorkshire, where he settled down very happily to country work. A man of upright, serious, and kindly character, he will be greatly missed. The sympathy of the profession goes out to the widow and two little children he leaves behind.—W. McK.

Universities and Colleges

ROYAL COLLEGE OF SURGEONS OF ENGLAND

Buckston Browne Dinner

The Buckston Browne Annual Dinner of Fellows and Members was held at the College on the evening of Nov. 15, when a large company was received by the President, Sir Alfred Webb-Johnson, and the Vice-Presidents, Mr. C. Max Page and Mr. W. H. Ogilvie. The principal guest was Viscount Addison, Secretary of State for the Dominions. After the health of the King as Visitor of the College had been honoured, the President began on a note of sorrow for the death of Sir George Buckston Browne in his 95th year on Jan. 19. This was the first of the dinners he endowed at which they had not had the pleasure of seeing and hearing him. Besides being a great and loyal friend of the College, Buckston Browne was one of its three most munificent donors, ranking with Sir Erasmus Wilson and Sir William H. Collins; his memory would always be honoured by Members and Fellows. The President greeted Lord Addison not only as a Minister of the Crown but as one of themselves present in his own right as a Fellow. This was a family party and also a house-warming, and he welcomed home those who had returned to civilian life, saying that the College was intensely proud of them. He quoted words spoken to him by Field-Marshal Montgomery in tribute to the medical and nursing services for their invaluable work in maintaining the morale of the Army. What of the College to which they had come back? It had suffered terribly by bombardment, but the foresight of his predecessor, Sir Hugh Lett, had saved much. Turning to Lord Addison, the President became for the moment an outspoken mentor of the Government on the essentials of a sound national health service, in which there must be the highest quality of professional work, freedom with reasonable discipline, and willing partnership. Lord Addison, after a tribute to the Medical Research Council, a body financed by the Government in which he had had a hand at the start, said that the beginning of a comprehensive health service would be an immense task, and to build it up would take years. Those members of the Government concerned in the matter knew the vital importance of giving incentive to efficiency and of gaining the good will of those who worked the service. Mr. Julian Taylor was called upon to say a few words about his experiences as a prisoner of war in the Far East, and paid a moving tribute to the medical men who worked with him in captivity.

Council Meeting

At a meeting of the Council of the College, held on Nov. 8, Diplomas of Membership were granted, jointly with the Royal College of Physicians of London, to R. H. B. Mills, J. D. Huntley, R. D. Price, and C. T. Ross, and to the 184 successful candidates whose names were printed in the report of the meeting of the Royal College of Physicians of London in the *Journal* of Nov. 3 (p. 630). Diplomas in Medical Radiodiagnosis were granted, jointly with the Royal College of Physicians of London, to G. A. D. Gordon, P. P. Hauch, W. J. Latham, C. F. Parry, and D. G. Wollin.

Mr. P. H. Mitchiner was re-elected a member of the Court of Examiners. Sir Frank Colyer was elected Charles Tomes Lecturer, and he will give two lectures on a dental subject in July, 1946. Dr. H. A. Sissons (Melbourne) was appointed a Leverhulme Research Scholar to work in the pathological department of the College.

The following hospitals were recognized for the resident surgical post required of candidates for the Final Fellowship Examination: Dudley Road Hospital, Birmingham, resident surgical officer and house-surgeon; Burton-on-Trent General Infirmary, resident surgical officer; Halifax General Infirmary, resident surgical officer and house-surgeon; Burnley Municipal Hospital, resident surgical officer.

UNIVERSITY OF OXFORD

Theodore Williams Scholarship in Pathology

There will be an examination for the Theodore Williams Scholarship in Pathology in the Sir William Dunn School of Pathology on Monday, Dec. 3, at 2 p.m. It will consist of a written paper and a viva voce examination. The viva voce examination for short-list candidates will be held on Friday, Dec. 7, at 2 p.m. The scholarship is open to any member of the University of Oxford, whether man or woman, who on June 30, 1945, had not exceeded twenty-six years of age and had attended a course in general pathology and bacteriology in the Sir William Dunn School of Pathology either in the academic year 1944–5 or in the academic year 1943–4. Those intending to present themselves for this examination should inform the Professor of Pathology before Wednesday, Nov. 28.

PSYCHOLOGY OF THE PROSTITUTE

The Psycho-Pathology of Prostitution. By Edward Glover, M.D. (Pp. 16. 1s.) London: Institute for the Scientific Treatment of Delinquency, 17, Manchester Street, W.1. 1945.

The International Bureau for the Suppression of Traffic in Women and Children convened in 1943 an international meeting to discuss the abolition of tolerated prostitution. On that occasion Dr. Edward Glover, one of the foremost exponents in this country of Freudian psychology, delivered this lecture, which has been reprinted by the Institute for the Scientific Treatment of Delinquency as a pamphlet. He describes shortly the infantile origins of sexual libido in the mouth, anal region, and genital organs, and shows how sexual perversions are a fixation in adult life of the libido at these infantile levels. Perverse practices play a large part in the activities of prostitutes, and this fact raises for him the question whether prostitution is not actually a regressive manifestation indicating a backward and retarded state of sexual development and possibly also a retarded general mental development. Further, Freud has taught that a normal part of a child's education is to separate the sexual or erotic aspects of infantile love from its idealistic or non-erotic aspects. When adult sexuality appears this cleavage must be overcome, or the adult will not be able to direct his sexual urges and his mental love feelings towards one and the same object. If the cleavage persists, he may feel an idealized love for one person but be able to enjoy sexual relations only with another person of inferior attributes. Many men of high intellectual and ethical development are sexually potent only with prostitutes, and for them the prostitute satisfies a psychopathological demand. Emphatically, Dr. Glover states, the problem of prostitution is two-sided, and not only the prostitute but also her clients must be psychologically examined if the problem is to be properly understood. He traces in a most interesting way the connexion between the familiar regressive patterns of psychopathology and the sexual and social behaviour of the prostitute, and shows how the environmental factors of a loveless home life, sexual irregularity in the girl's parents, and economic insecurity contribute to the situation.

Convinced that prostitution expresses a sexual and social backwardness in both parties, he objects to tolerated prostitution because it tolerates the problem as well as the prostitute—gives social sanction to a pathological condition. He adds a pertinent criticism of the present legal procedure for dealing with prostitutes, and a caution on the limitations of the psychological expert witness. This, in short, is a sound and helpful pamphlet.

TUBERCULOSIS IN THE U.S.A.

Tuberculosis in the United States. Graphic Presentation. Vol. 2. Federal Security Agency, U.S. Public Health Service, and Medical Research Committee, National Tuberculosis Association, Washington, 14.

The lack of knowledge of the population exposed to risk in age groups in wartime makes a detailed examination of death rates an impracticable proposition. The difficulty has been partly overcome in this volume by the use of proportional mortality. Deaths from all forms of tuberculosis expressed as a percentage of deaths from all causes have been tabulated in twelve age groups for each State and geographic division by sex and race. The periods covered are the triennia 1939–41, 1929–31, and 1919–21. A comparison of the trends for each area has been made in two diagrams, one showing the distribution by sex and race in age groups for 1939–41 and the other the distribution by age in the three triennia. The proportional mortality during the twenty years has declined by more than a half for the white population, from 8.2 to 3.6, but the decline has been slower for the non-whites, from 15.3 to 9.3. Tuberculosis was responsible for a greater percentage of the total deaths among the young non-whites than among the white population; for the age groups 5–9, 10–14, and 15–19 the percentages for the former were, for both sexes, 10.5, 18.6, and 32.5, compared with 2.8, 3.9, and 10.2 for the latter. This racial difference affects the attempt to standardize for age and leads to a slight increase in the rate for the white population and a large decrease in the rate for the non-white population; the crude rates were respectively 3.6 and 9.3, and the standardized rates were 3.8 and 5.9.

Notes on Books

There is little to criticize and much to admire in the fourth edition of Prof. WILLIAM BOYD's *Pathology of Internal Diseases* (Henry Kimpton; 50s.). Few medical books are so readable or more skilfully illustrated. Whilst recent discoveries in pathology are well reviewed and recorded, the author points out, in no uncertain way, the larger gaps in pathological knowledge, especially when no adequate structural changes have yet been found to account for grave and common disorders of function. We are, for example, reminded, with regard to the myocardial lesions of acute rheumatism, that "the changes in the muscle fibres are peculiarly disappointing and fail to explain the cardiac failure of the acute stage," and "it is evident that the technique of the pathologist is inadequate for estimating the functional capacity of the myocardium." The references in this, as in previous editions, are well chosen, and the volume remains convenient in size, weight, and make-up.

People who Live in Glass Houses is a ninepenny booklet of some 80 pages which looks at venereal diseases from both the medical and the lay points of view: it tells the man in the street just those things about the subject of which he is usually quite ignorant; it tells him enough without trying to tell him too much. For the most part the approach is straightforward and the language simple, though occasionally Mr. HAROLD THOMAS lapses into terms which are rather too technical. The whole subject is set out clearly and dealt with in human fashion; there are a few minor errors which detract little from the value of the book. The one thing that appears to be open to criticism is the title; surely something more arresting and descriptive could have been found; numerous ones suggest themselves—"The Danger in our Midst" or "The Hidden Scourge," for example. What really matters is how this excellent little publication is to be "got over" to the public; in our view a copy—or several—should be placed in every public library and reading-room throughout the country. We commend this suggestion to the Central Council for Health Education, which issues the booklet from Tavistock House North, Tavistock Square, W.C.1.

The issue of Memorandum 266/T by the Ministry of Health was generally welcomed as a great step forward in the provision of facilities for early diagnosis and the official recognition of the relation between the tuberculous patient's financial anxiety and his willingness to accept treatment. There was, however, widespread disappointment at the exclusion of the non-pulmonary cases and the so-called "chronic" cases. The Joint Tuberculosis Council set up a committee to consider the memorandum, and its interim report has now been published as a pamphlet. Copies may be had from the hon. secretary of the J.T.C., Dr. N. J. England, 1, Becket Street, Oxford.

The *League of Red Cross Societies' Bulletin* for July–September, 1945, contains extracts from the report of the Secretary-General of the League to members of the executive committee on work done during the first six months of the year. The end of hostilities, far from diminishing the tasks and responsibilities of the Red Cross, has increased them. The *Bulletin* is published every three months in English, French, German, and Spanish from the headquarters of the League, 8, rue Munier-Romilly, Geneva; annual subscription 2s. 6d., or 50 cents.

Preparations and Appliances

A SIMPLE APPARATUS FOR PENICILLIN ADMINISTRATION

Dr. A. J. P. GRAHAM, resident surgical officer, Royal Surrey County Hospital, Guildford, writes:

Several types of penicillin administration apparatus have already been described in medical journals, each making legitimate claim to some improvement or advance over those already in use. Experience of some of the present difficulties and disadvantages associated with intermittent administration of penicillin has led me to review the methods employed and reconsider their value. The introduction of another new method would have to be based on convincing evidence of its superiority to those already employed. It would have to overcome at least some of their disadvantages and be founded on clinical trial and proof. Moreover, it would require to be simple in construction and easy to use, because with the increasing availability of the drug in its present form complicated methods of administration would merely increase the work of the nursing staff. Until penicillin is administered less frequently in an oil base, or by mouth, the intermittent systemic injection therapy has to be relied on for most purposes.

Probably owing to impurities in the drug, intramuscular injection is painful, and after receiving repeated three-hourly injections the patients frequently come to dread them. Some

UNIVERSITY OF LONDON

The following candidates have been approved at the examination indicated:

THIRD M.B., B.S.—[1,5] K. E. Cooper, [1,4] J. Luder, [1,2,3,5] J. Swale, [1,3] R. W. E. Watts, Mary C. V. Alabaster, K. D. Allanby, P. S. Allenby, Sheila W. Anderson A. R. Anscombe, G. J. E. Ansell, R. N. Austin, G. M. Bailey, Agnes W. Baker, P. B. Banaji, D. N. Baron, H. F. McG. Bassett, Joan R. K. Bastable, R. A. Boland, G. E. Bond, Lesley M. McL. Bowen, A. F. Bromwich, D. E. M. Brown, A. J. Buller, Joyce B. Burke, D. E. St. J. Burrowes, M. F. Butler, M. Caine, K. A. A. Campbell, K. H. Chin, C. J. M. Clark, K. S. Clarkson, Sylvia D. Corben, A. V. Craig, A. R. Darlow, Elizabeth E. Davies, J. S. Davis, S. Davis, J. W Dickson, Aileen P. M. Dring, Kathleen A. D. Drury, E. M. C. Dunlop, Viola M. Frymann, Joan R. Gomez, G. E. Griffiths, G. R. S. Grogono, V. L. Guillem, Ruth A. Haes, Kathleen M. Harding, W. J. Ll. Harries, M. A. Harris, W. C. Harris, L. M. Harrison, W. E. Hassan, Audrey Hazelden, Josephine M. R. Heber, Joan F. Heffernan, A. R. Helm, J. Henneman, M. D. Hillel, B. H. Hogben, J. E. Holgate, E.-R. A. C. Hollingbery, Margaret E. Holness, Pamela M. Horne, Betty E. Howarth, J. D. Huntley, A. F. Huston, Patricia L. Hutchinson, M. S. R. Hutt, Ruth C. J. James, R. M. Jenner, R. G. G. Jones, T. J. Jones, H. E. M. Kay, M. B. King, S. Lall, Jean V. Lang, V. B. Levison, J. W. Lewis, Jeanne C. Lister, Helen M. Littler, Joan V. Thomas, Phyllida M. M. Thornton, D. E. Truscott, Kathleen L. Turner, P. P. Turner, R. S. Walker, P. T. J. C. P. Warner, A. D. Weatherhead, R. G. Welch, O. G. Williams, F. R. M. Young, R. Youngman.

[1] With honours. [2] Distinguished in pathology. [3] Distinguished in hygiene and forensic medicine. [4] Distinguished in medicine. [5] Distinguished in applied pharmacology and therapeutics.

UNIVERSITY OF DUBLIN

The Board of Trinity College, on the nomination of the University Council, has appointed Prof. R. A. Q. O'Meara, M.D., Sc.D., F.R.C.P.I., to the chair of pathology in succession to Prof. J. T. Wigham, M.D., F.R.C.P.I., who has resigned. Dr. O'Meara was elected a Fellow of Trinity College in 1941, and in the following year was appointed to the chair of experimental medicine.

The Services

Capt. R. H. S. Lee, R.A.M.C., has been appointed M.B.E. (Military Division) in recognition of gallant and distinguished services in the field.

The following appointments and awards have been announced in recognition of gallant and distinguished services in Burma:

C.B.E. (*Military Division*).—Brig. (Local) J. Bruce, Brig. (Acting) I. G. W. Hill, T.D., and Brig. (Temp.) D. F. Panton, R.A.M.C. Col. (Temp.) W. A. Burki, M.B.E., I.M.S.

O.B.E. (*Military Division*).—Lieut.-Cols. (Temp.) H. Gass, G. G. Mer, J. H. Moffett, T. A. Pace, and A. V. Stevens, *M.C.*, R.A.M.C.

M.B.E. (*Military Division*).—Lieut.-Col. (Acting) W. H. Wolstenholme, Major (Temp.) A. Milne, and Capt. P. J. R. Davis, R.A.M.C. Lieut.-Col. (Temp.) S. M. Paw, Army in Burma Reserve of Officers.

Bar to the D.S.O.—Major (Temp.) B. G. A. Lilwall, D.S.O., R.A.M.C.

M.C.—Capt. A. M. Ogilvie, R.A.M.C. (killed in action).

The following have been mentioned in dispatches in recognition of gallant and distinguished services in North-West Europe: Brig. (Temp.) Q. V. B. Wallace, C.B.E., M.C., late R.A.M.C., Brig. (Temp.) A. E. Porritt, C.B.E., Brig. (Acting) G. K. Fulton, M.B.E.; Cols. (Temp.) K. Fletcher-Barrett, O.B.E., R. Rutherford, T.D., and I. A. M. Paton, O.B.E.; Lieut.-Col. G. B. Mitchell-Heggs, O.B.E.; Lieut.-Cols. (Temp.) J. C. Caird, S. J. Chesser, M.B.E., P. J. H. Clarke, T. H. Crozier, E. A. Jack, O.B.E., R. B. Myles, O.B.E., R. W. Power, T.D., and K. G. W. Saunders; Lieut.-Col. (Acting) R. G. Evans, M.B.E.; Major J. S. Kelleher; Majors (Temp.) P. M. Acheson, A. K. Borland, M.B.E., D. S. Buchanan, G. P. Charles, A. E. Cooper, M.C., A. B. Donald, G. B. Forbes, W. Hobson, J. S. Lancaster, M.C., J. L. Linacre, B. T. Mann, E. H. Moore, J. F. D. Murphy, W. A. B. Nicholson, R. F. G. Ormrod, T. G. Risley, T. D. Ross, W. C. Ross, J. E. Semple, K. D. Stewart, M.B.E., G. F. Valentine, A. W. J. Kirton-Vaughan, L. B. Wevill, A. Young, and J. M. Zabokrzycki; Majors (Acting) D. J. A. Alban-Jones, T. Black, and N. A. Mossendew; Capts. G. L. McC. Blair, J. Booth, E. M. Callander, S. H. Chazen, R. B. Coles, E. G. A. Crawshaw, J. B. Farquhar, R. W. L. Hall, E. B. Harrison, F. J. Hebbert, B. C. H. Luker, B. W. MacDonald, J. S. MacRae, J. S. O'Dwyer, J. Y. W. Russell, K. E. Rymer, J. Slater, R. S. Sunderland, and H. B. Young; Lieuts. W. Brownsey, P. A. Hann, P. F. Holley, D. G. Jones, J. G. Searle, and J. K. Tizard, R.A.M.C. Lieut.-Cols. H. A. Ansley, G. A. Copping, F. G. Kergin, and F. W. Schroeder; Majors C. W. Dales, F. J. McLean, J. H. Shaw, and J. E. Williams; Capts. R. E. Bell, A. E. Conley, N. C. Delarue, A. C. Derby, C. M. Leighton, A. H. MacLennan, R. E. G. Place, and J. C. G. Young, R.C.A.M.C.

Repatriated.—Fl. Lieut. F. A. Forbes, R.A.F.V.R.; Capt. J. F. McGarity, I.M.S.

Medical Notes in Parliament

Conditions in Mental Hospitals

Mr. JOHN LEWIS opened on Nov. 6 a discussion on mental hospitals. He said that this year approximately 127,000 persons suffering from mental disorders were in our hospitals and homes. The majority were treated in wholly or partly rate-aided institutions. The staffs of these institutions worked under most difficult conditions due to lack of accommodation and understaffing. It was only possible for them to skim the surface of treatment because their time was taken up in ordinary routine. The big figure he had given for people in these institutions represented only a fraction of those in need of mental treatment and attention. Psychoneuroses occurred in 2% of the population. General practitioners said that 30 to 50% of their practice was concerned with people suffering from functional nervous disorders. In general hospitals 17% of those referred to general medical out-patient departments suffered from psychological illness without serious organic component.

What inducement was there for patients to enter mental hospitals to-day voluntarily to receive treatment? The remoteness of the places, with high walls, bleak premises, and locked doors, made clear to those able to think that those entering might never return. This was despite the fact that 40% of patients who entered mental institutions returned to their family cured, and 20% returned home much improved. These figures were more encouraging because people very often came to mental hospitals in a late stage of mental illness and often in the last stages of senile dementia. In mental hospitals 70% of the inmates suffered from chronic or senile dementia and could not benefit from any form of treatment other than care and attention, which were lavished on them by a devoted staff. To amend the system public opinion must be educated.

There were approximately 1,000 to 3,000 patients in the average mental hospitals. Fever hospitals had 144 sq. ft. per bed, general hospitals 120 sq. ft., but mental hospitals only 50 sq. ft. In some parts of these hospitals beds were so close together that it was impossible to stand between them. The most terrible indictment of the system was the mortality from tuberculosis in 1942 in mental institutions, which was fifteen times as high as in the normal population. These high figures had been reduced where the overcrowding had been reduced and where the diet had been improved. There was no reason why the incidence of tuberculosis in mental institutions should be higher than among the normal population. Most of the hospitals were very old and out of date; patients were not classified according to their type of mental disease but, as a rule, by their degree of physical infirmity, by the degree of noise, and by habits—whether clean, dirty, destructive, or violent. Epileptics and potential suicides were scattered throughout the whole hospital.

In many hospitals true convalescent wards did not exist. Patients who were presumed to be convalescent were usually sent into the admission ward, but often into the chronic wards if the permanent residents were clean and quiet. This atmosphere was not encouraging for the patient trying to adjust himself to normal circumstances. Hospital wards were largely utilized for the chronically infirm and not for patients who came for treatment. They might include people who had been bed-ridden for 50 years. These were not the proper conditions in mental institutions for people who were actually ill and needed treatment.

The patients in most institutions were fed from centralized kitchens and the food often arrived cold. The low standard of diet had its origin in the fact that years ago it was believed that low feeding would keep a patient quiet. That system still operated to-day in some places. So far as the medical staff was concerned the average was 1 doctor to from 300 to 700 patients. That was insufficient to allow doctors time for research in psychiatry. Patients who could afford to pay had more cheerful surroundings and better furniture but no better treatment because it was not available. Much more money must be provided for improved treatment, nursing, surroundings, and research. Two categories of mental hospitals should be built: those to deal with the 70% of chronic cases which would not improve; and those for the treatment of acute cases, in which the most modern scientific methods would be employed. It would not be necessary to discard the present institutions. Inmates who could not benefit from treatment should be left to end their days there. New hospitals must be built near to universities or medical schools. A medical superintendent should be a teaching member of the university. Where there was no chair of psychiatry one should be established; there

D-Day casualties were reduced to tears after two or three days' penicillin treatment, while administering it to young children is often not a pleasant procedure for the nurse. Use of the gluteal region, besides being anatomically unsound, may after repeated administration become so painful that patients cannot lie comfortably. Intermittent injection directly into the patient disturbs his sleep at night, both by the pain and by the ritual. This is most undesirable in those who are seriously ill, and should be avoided. It can be materially reduced by a continuous intramuscular drip, which, however, requires constant care and attention. Drip apparatus is usually an encumbrance to patients, is more complicated and liable to lead to waterlogging of the tissues, and is responsible for some loss of potency of the penicillin owing to the length of rubber employed and the failure to keep the drug at its most stable temperature. It has, however, the advantage of administration into the thigh muscles and is very useful for infants and children and domiciliary treatment.

Cowan[1] has published figures showing the destruction of penicillin by rubber tubing. In continuous intramuscular infusion as much as 25 to 50% of penicillin may be rendered inactive by the rubber, so it would appear obvious that the shortest possible length of rubber tubing of any kind should be employed. Stammers[2] and Morgan Thomas[3] recently emphasized this point and advocated an administration apparatus incorporating shorter lengths of rubber than those used in the types described by Ronald Edwards[4] and Last.[5] The tubing supplied with the Riley thoracic aspirating device used by Edwards with his bottle and syringe apparatus has a thick wall allowing repeated puncturing without leaking. Edwards uses it in twelve-inch lengths holding approximately 3 c.cm. Using penicillin solutions made up to 20,000 units per c.cm. it is seen that after the first dose has been injected the next dose is in contact with rubber for three hours before reaching the patient, and each subsequent dose lies in the rubber tubing for six hours before entering the tissues. In this time the potency may diminish by 50% if the rubber is of the synthetic variety. From clinical results obtained with the use of this instrument it would appear that the actual loss of potency under ordinary conditions is less than estimated, or alternatively that the recovery from infection was not so largely due to the penicillin. The logical deductions from calculated data, however, strongly advocate the use of as short a length of rubber tubing as possible and a continuation of the method of storing penicillin solutions in the cold.

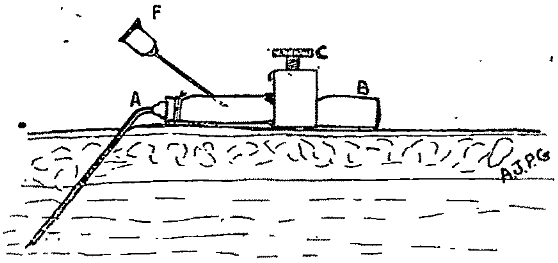


FIG. 1.

Of the types of apparatus already described, only that of Milles[6] meets the last two requirements, but it has the disadvantage of being rather too complicated from the nursing administration point of view and too liable to contamination if not carefully used. As these factors are of sufficient importance to warrant the introduction of yet another instrument to be added to our surgical armamentarium, it was decided to attempt to produce one that would fulfil as many of the ideal requirements as possible. The ultimate design that this took reached its present form as the result not of backroom planning but of clinical trial and error. It does not claim to be perfect, but as a means of administering penicillin intermittently during the interim period until the drug is produced in some other form, free from painful properties, or until solution in oil does away with the need for frequent administration, it is of great value. To some its use may transgress the borders of general surgical principles, but the relief from pain, the apparent therapeutic success that has attended it, and the almost entire absence of complications that has ensued, lead one to believe that its use is justified.

The apparatus employed is extremely simple, but certain of the features are essential to its success. It can be made in any ward.

Requirements.—A needle (A) about two inches long with a fairly wide bore. A narrow-bore needle prevents free injection into the tissues and conduces to leaking. The needle is bent about 45° just beyond its base, so that the point will penetrate well into the muscle when the rubber is strapped to the thigh. Two inches of rubber tubing (B) with a wall having a thickness of at least 2 mm. The type of tubing supplied with the E.M.S. blood transfusion set is not thick-walled enough for the purpose, as it allows of subsequent leaking after repeated punctures. One end of the tubing is fitted over the needle mounting and tied on tightly with silkworm gut. A screw clip (C) of any type is fixed on so as to allow half an inch of tubing between it and the needle. This must be screwed on firmly to occlude the lumen. The volume of the lumen between clip and needle varies with the internal diameter of the rubber, but with one of 4 mm. it is about 0.157 c.cm.—i.e., less than one-sixth of the volume of a dose of 20,000 units in 1 c.cm. This is the whole apparatus.

Application.—After being sterilized it is applied to a suitable area on the anterior or lateral aspect of the thigh and fixed on with two strips of adhesive plaster (D) as shown in Fig. 2. No advantage is gained by inserting the point of the needle through sterile gauze, but a small piece may be placed under the rubber and clip if this adds to the comfort of the patient. A rather broader strip of strapping (E), with a small piece of sterile gauze covering the middle third on the adhesive surface, is then fixed transversely across the apparatus.

Use.—One end of the broad strapping is turned back, uncovering the apparatus. The required dose of penicillin is taken up into a syringe in the ordinary way and, using a fine hypodermic needle (F), is injected obliquely and slowly into the lumen of the rubber tubing between the clip and the intramuscular needle. The rubber is, of course, swabbed with aether meth. first, as the skin would be. After the hypodermic needle is withdrawn the broad strapping is replaced. For the first dose 0.2 c.cm. of penicillin is added to fill the free space of the lumen. A small cradle over the leg facilitates injection at night with less disturbance to the patient.

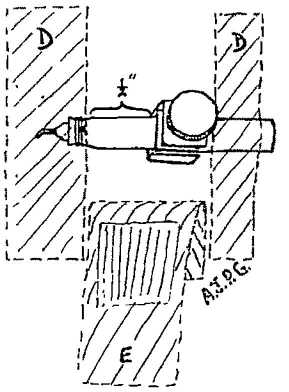

FIG. 2.

Advantages of this Method.—The apparatus is easily made and simple to use. It makes penicillin administration less painful and less disturbing to the patient. The first injection is quite as painful as with other methods, but each subsequent dose is very much less so and is often quite painless. Owing to the small amount of penicillin in contact with rubber and the ability to give it in the cold, the loss of potency is much less and is calculated to be about 4% instead of 25 to 50% as with some intramuscular infusion methods. Waterlogging of the tissues and needle-block do not occur. Its simplicity in use has all the advantages of hypodermic administration for the nursing staff, without any of the disadvantages for the patient.

Disadvantages.—Some patients find it an encumbrance to have even such a small gadget strapped to them. Leakage may occur if the tubing is too thin, or the needle too narrow, or the injection made too quickly. Repeated puncturing at the one site may be eliminated by turning the rubber 90° in relation to the needle or by attaching it by the other end of the tubing. After two days the site of injection may again become painful, necessitating removal and reinsertion at a fresh site. One small *B. coli* abscess has occurred at the site of injection.

My thanks are due to the sisters and nurses of this hospital for their co-operation and helpful suggestions.

should be teaching hospitals in the vicinity with adequate out-patient facilities and a psychiatrist provided by the mental hospital. There must be two classes of nurses, one of which would look after chronic patients. Criticizing the present method of certification whereby the general practitioner called in the relieving officer and the patient might be brought before a magistrate without the advice of an outside doctor, Mr. Lewis said that in his own constituency it was the practice of the magistrate to bring with him an outside doctor for certification.

LACK OF ACCOMMODATION FOR NEUROSES

Dr. STEPHEN TAYLOR agreed in general with Mr. Lewis, but said he had over-painted the picture. Many mental patients got tuberculosis because it was extremely difficult to feed those who were suffering from depression. The incidence of this disease in mental hospitals could not be blamed on the staff or the facilities. The overcrowding had been due in part to the existence of the E.M.S., but was a serious factor in mental treatment at the moment. The temporary treatment section of the Mental Treatment Act did not work badly and enabled enormous numbers to be treated in mental hospitals without certification. There was a great shortage of out-patient or advisory clinics, and in-patient facilities for the neurotically ill scarcely existed. With the exception of the Maudsley Hospital serving South London there were mostly no beds for neurotic patients. General hospitals should have admission blocks for all types of psychiatric patients where people could be treated and put into their appropriate classes. The old-fashioned mental hospital was an anachronism. If the country was to have mental hospitals they should be small units, perhaps the size of the Bethlem Royal Hospital, with 250 beds where a medical staff could properly look after the cases. More could be done by boarding out the chronically insane for whom further treatment was not possible.

The country was short of adequately trained general practitioners who could make a psychiatric diagnosis. As psychiatrists came from the Forces this could be made good, but it would be 20 years before every general practitioner could make a good psychiatric diagnosis unless refresher training for general practitioners was started quickly. The country was short of research centres. The Tavistock Clinic should be developed. The national psychiatric service could only be dealt with as part of the main National Health Service and needed to be tackled on the same lines as other specialized services with out-patient facilities and specialists to visit the home. Voluntary registered mental hospitals such as Bethlem and the Retreat at York should be brought into a National Health Service, but he did not know how this should be done. Of the private mental hospitals run for private profit some were all right but some were far from right. Broadmoor, which was not a Ministry of Health concern, was an anachronism, a bad place for the patient, and a terrible strain on the staff. Its patients should be put under the ordinary service. The staff of the mental hospital service were isolated spiritually and physically. The remedy was to move them about between the general hospitals, the epileptic hospitals, the mental defective colonies, and even the prison medical service.

Replying for the Ministry of Health, Mr. KEY said he would be the last to assert that everything was well with the mental hospital services. He had nothing to say in favour of the Poor Law atmosphere, which existed around a number of these institutions, but the problem was not best dealt with by exaggerating the conditions. What had been said in the debate would be carefully considered in connexion with the organization of the health service to which Mr. Bevan was giving attention. Mr. Key pointed out that the number of people under care had fallen between Jan. 1, 1939, and Jan. 1, 1945, from 133,000 to 127,000. The general improvement in the social standards of the people resulting from continuity of employment had led to a decrease in mental illness. One of the ways of tackling the problem was to maintain the general standard of life. The overcrowding in institutions resulting from the transfer of beds to the E.M.S. was beginning to remedy itself. Between Jan. 1 and Oct. 1 this year 2,273 beds had been restored to the mental hospital service.

The number of people now training for the nursing profession was greater than it had ever been, and the shortage of nurses was due to the increase in such services as day nurseries and radiography. He thought it was wrong to say there was no reason why there should be no more than a normal rate of tuberculosis among people in mental hospitals. These people were spending too much of their time in institutions and so they had a predisposition towards this disease. But since 1941–2 there had been a decrease not only in the incidence of tuberculosis but in its death rate among those in the institutions. Of the 101 public mental hospitals in this country 60 had provided separate admission units and separate convalescent units. With the return of peace and more staff, conditions would greatly improve. He could not agree that diet in these institutions had been brought down to the public assistance level. The steady reduction of the death rate was partly due to the attention given to the diet. Of patients who had been admitted or were being admitted now nearly 50% were voluntary patients. That number would not go to the hospitals if the black picture that had been painted was really indicative of the conditions.

Medical Man-power: British and Alien

Major SYMONDS asked on Nov. 8 how many doctors of British nationality were engaged in civilian practice in England and Wales and the average number of patients per doctor. Mr. BEVAN replied that the last analysis made by the Central Medical War Committee in February related to all doctors on the permanent *Medical Register* without distinction according to nationality. It showed that the number of doctors in civilian practice of all kinds in England and Wales was 27,177, or in general practice only 14,337, representing a ratio to civilian population of one to 1,393 and one to 2,640 respectively. The number of temporarily registered alien doctors in employment, including a few in Scotland, was 798. Nearly half of these were of German or Austrian nationality. The next largest groups were Czechs and Poles. He was unable to give the average age, but 525 out of the total were over 40. He had no information on how many temporarily registered alien doctors had returned to their own countries nor on how many were likely to do so in the near future.

Major SYMONDS also asked whether the Minister, in view of the shortage of doctors, was taking steps to ensure that the Temporary Registration Order of 1941, by which refugee doctors were permitted to obtain posts in hospitals or to work as assistants to medical practitioners, was extended beyond Feb., 1946. Mr. BEVAN pointed out that the Emergency Laws (Transitional Provisions) Bill included provisions for the continuance of the Order beyond the date mentioned.

It was stated by Mr. EDE that among the doctors in South Wales at present were six Austrians (two of them women), three Germans, and one Czechoslovak. The three Germans and the two Austrian women were on the register of persons who were only permitted to take certain limited forms of medical work. Seven of these doctors had applied for naturalization, but their applications had all been suspended in accordance with the general policy that had been in operation since 1940.

Call-up of Doctors

On Nov. 15 Col. STODDART-SCOTT asked the Minister of Health why, in view of the fact that there were 2.57 doctors per 1,000 in the Army and 2.27 doctors per 1,000 in the R.A.F., and only 0.74 per 1,000 in the civil population, over 370 doctors had been called up into the Army and R.A.F. since VE-Day; and why they were still being called up in considerable numbers. Mr. BEVAN answered that continued recruitment of doctors to the Forces was necessary in accordance with the general principles set out in the White Paper on the Reallocation of Man-power issued in Sept., 1944, in order to increase the releases of medical officers under Class A of the demobilization scheme and to compensate for releases under Class B. The great majority of those called up were young men recently qualified who had held hospital appointments for six or twelve months.

Short-service Commissions and Release

Mr. LAWSON informed Mr. Lipson on Nov. 13 that a doctor appointed to a short-service commission before the war was liable to retention during the present emergency under Article 213 of the Royal Warrant for Pay, etc., of the Army, and was retained subject to the conditions which Mr. Lawson had previously set out. A doctor appointed during the war was eligible on completion of his period of five years' short-service commission for immediate release if his age-and-service group had already been released, or alternatively for release with his age-and-service group when it was reached, provided he had not been appointed to a permanent commission and had not applied to defer his release or to serve on for a minimum period of two years' post-war service with gratuity.

Foot-and-mouth Disease from Butcher's Meat.—Major TURTON on Oct. 15 asked the Minister of Agriculture what action he proposed in view of the warning given by the chief veterinary officer on May 4, 1945, of the danger of outbreaks of foot-and-mouth disease occurring on the premises of butchers distributing South American meat. Mr. TOM WILLIAMS said the only practicable way in which the danger could be reduced was by observing and enforcing the existing regulations. Every effort to secure stricter enforcement was being made, and with some apparent success. There had been only two outbreaks of foot-and-mouth disease so far this year on butchers' premises, and three others that might in some way be associated with butchers.

BUYING AND SELLING PRACTICES

Mr. Willink, as Minister of Health in the late Coalition Government, announced that in its plans for a new health service the Government did not intend to interfere with the custom of buying and selling practices, and this policy was presumably supported by the Labour members of the Coalition Cabinet. Men now being demobilized are entering general practice on this basis. It has been said that the present Minister of Health, Mr. Aneurin Bevan, will make a further statement on this subject, and it is not improbable that if he does the Coalition policy may be reversed. If it were, it is of course presumed that a statement would at the same time be made on the question of compensation for the loss of capital value. Although in this world of shifting values it is perhaps unwise to take anything for granted, it would seem to be a simple matter of equity for compensation to be paid if sale and purchase of practices were to come to an end. The medical profession could tolerate no other course.

If the question of buying and selling practices was just one of finance, then, although there might be differences of opinion about it, they should not become so acute as to split the profession or to erect an insuperable barrier between the profession and the Minister. This custom is not *necessarily* bound up with the essential freedom of the doctor to practise according to his professional conscience and knowledge. In fact, men in some Dominions can enter a practice without having to buy it, and it should be remembered that at the moment there is nothing to prevent a man in this country from starting a practice of his own without having to find the capital to do so; although, of course, he has to have enough money on which to live until his practice is established. When by dint of hard work and professional competence a practitioner has secured the confidence and good will of the local community in which he lives, he has, towards the end of his working life, a natural wish to be compensated for his efforts when he hands on the goodwill and reputation of the practice to his successor; and his proper pride in his work, coupled with a responsibility towards the patients who constitute his practice, prompts him to choose as his successor the kind of man who will best fit in with the life of the district. The essence of the matter is the freedom to practise, and the freedom to choose as a partner and successor in this venture a man who is trusted both professionally and on the grounds that he is the kind of person who will be in sympathy with the kind of patient whom the practice attracts. If these essential freedoms could be left unchanged by the abolition of the right to buy and sell practices there would be no interference with professional principle, whatever views anyone might hold on political and social grounds about the right of a man to possess his own property—in the case of a general practice, represented principally by goodwill.

But if the Government were to decide to abolish this right, would it do so with the intention of leaving unchanged what we regard as fundamental principles? In the conditions prevailing in Great Britain, is the custom of buying and selling in fact bound up with professional freedom, and would this be endangered if the custom were brought to an end? In examining this question we should not ignore the difficulties facing a young man who wants to enter general practice in the accepted way. In these days the difficulties are considerable. The man who starts off with money of his own has an advantage over the man who has not, and a man may be a good doctor but yet be unwise in taking financial decisions. At least to-day he is in a better position than his forebears, because the B.M.A. can give him competent advice on the matter, and see that he can borrow money at low rates of interest. But even then the young man with a family is faced, in these days of heavy taxation, with a debt to repay, and he would naturally be glad to avoid that if he can. So simply from the financial point of view the young doctor would welcome a way out of that method of entering practice. But the first question he should ask himself is whether, given this opportunity, he would simply be exchanging one burden, which is measurable, for another which is possibly immeasurable; whether, in an insecure world, he is trying to buy imagined security at too great a price; whether an easier time in his younger days would not be offset heavily by disappointment and disillusionment when the peak of middle age is passed.

Supposing the Government does decide to abolish the custom of buying and selling practices and, through compensation, becomes the purchaser, and therefore owner, of those practices, what becomes of the men who are thus compelled to sell their "work-right"? Who will decide thereafter who should continue these practices so dissolved? It is unlikely to be the men who have sold them, because according to ordinary usage a man who sells something no longer has a right in it. And if the professional right to practise in such-and-such a place in such-and-such a way is surrendered to the Government the Government will use what is surrendered in any way it sees fit; and in the case of the present Government we should at least not be misinformed on what ways it considers to be fit. It might use the property so disposed of to control the entry into practice and to distribute doctors according to its own ideas. In other words, any decision of the Government on the custom of buying and selling practices cannot be isolated from the context of the Bill for a National Health Service which in the months to come will be presented to Parliament. We cannot look upon it, for example, purely as a financial measure, but must first and foremost look upon it as closely bound up with the way in which practice is conducted and with the principles governing such practice. The public whom the medical profession serves may well ask themselves whether, in using the taxpayer's money to

Leprosy in British Empire.—Mr. GEORGE HALL said that although accurate figures were not available it was estimated that out of 2,000,000 lepers in the British Empire 700,000 lived within the Colonial Empire and the greater part of these in Nigeria. In that colony a big antileprosy campaign was being undertaken. Application by the Nigerian Government for a further £170,000 for the Colonial development and welfare work was under consideration. The Government hoped to provide more money in the future.

Analgesia by Midwives.—Mr. BUTCHER inquired on Oct. 25 what amendments had recently been made by the Central Midwives Board to their rules concerning the presence of a second person at the time of administration of analgesia for the relief of pain during childbirth. Mr. BEVAN said the rules were, with his assent, being altered to permit the second person to be anyone acceptable to the patient and considered suitable by the midwife. The requirement that the second person must have a specified qualification or experience was being withdrawn.

Totally Blind War Casualties.—Some 350 Service men and women were totally blinded during the war and are in receipt of 100% disability pensions.

Notes in Brief

Medical information disclosed by a Ministry Medical Board is not refused to a member of the medical profession if needed for treatment purposes. Where there is an appeal to the Pensions Appeal Tribunals an appellant is supplied with a statement of the relevant facts of his case, including his medical history as known to the Ministry of Pensions.

High-extraction and wholemeal flour are available to all bakers at the same price as National flour.

EPIDEMIOLOGICAL NOTES

Discussion of Table

In *England and Wales* measles and scarlet fever were more prevalent, the rises over last week's totals being 74 for measles and 65 for scarlet fever. There were 89 fewer cases of acute pneumonia, and 36 fewer of dysentery.

The largest local rise of scarlet fever was in Staffordshire, where the total went up by 37. The chief feature of the returns for measles was a rise of 37 in Carmarthenshire (Llanelly R.D. reported 22 cases). Yorks West Riding reported 33 more cases of whooping-cough than last week, and London 26. Diphtheria notifications in Lancashire went up by 25, the disease having increased 100% in this county since the beginning of August, compared with 62% for the whole country.

The only fresh outbreak of dysentery of any size was in Sussex, Chichester M.B. 12. The other large returns were Lancashire 49, London 40, Warwickshire 27, Glamorganshire 10.

In *Scotland* notifications of dysentery and acute pneumonia went up by 23 and 27 respectively, but decreases were reported as follows: scarlet fever 36, measles 19, whooping-cough 13. Edinburgh reported 10 more cases of dysentery than last week, and Glasgow 17.

In *Eire* the incidence of diphtheria went up by 33, and measles by 59. The rise in diphtheria was general throughout the country, but the increase in measles was due to Dublin C.B., where the notifications rose from 42 to 90.

Annual Report for Northern Ireland, 1943

The birth rate was 24.2 per 1,000 during the year, and was the largest rate recorded since 1920. Infant mortality was 78 per 1,000 births, and, with the exception of 1940, when the rate was 86, was slightly higher than any since 1936. Maternal mortality was 3.17 per 1,000 births, and, with the exception of 1942, when the mortality was 2.96, was the lowest on record. The general death rate was 13.4 per 1,000, this being 0.1 above the record low rate of 1942. The death rate for all forms of tuberculosis was 91 per 100,000, compared with 104 and 97 in the two preceding years.

Quarterly Returns for England and Wales

The birth rate during the second quarter of the year 1945 was 16.6 per 1,000, compared with 18.9 for the June quarter of 1944, and 15.9 for the average of the five second quarters preceding 1944. Infant mortality was 41 per 1,000 live births, this rate being 11 below the average of the ten preceding June quarters. The general death rate was 10.5 per 1,000, compared with 10.9 for the second quarter of 1944; there were 4,982 fewer deaths than the average of the second quarters for 1939–43.

Week Ending November 10

The notifications of infectious diseases in England and Wales during the week included: scarlet fever 1,621, whooping-cough 1,118, diphtheria 573, measles 445, acute pneumonia 463, acute poliomyelitis 33, cerebrospinal fever 37, dysentery 212, paratyphoid 5, typhoid 2. Three cases of typhus fever were notified: London, Hampstead 1, and Kent, Royal Tunbridge Wells M.B. 1, and Tonbridge R.D. 1.

No. 44

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended Nov. 3.

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for: (a) England and Wales (London included). (b) London (administrative county). (c) Scotland. (d) Eire. (e) Northern Ireland.

Figures of Births and Deaths, and of Deaths recorded under each infectious disease, are for: (a) The 126 great towns in England and Wales (including London). (b) London (administrative county). (c) The 16 principal towns in Scotland. (d) The 13 principal towns in Eire. (e) The 10 principal towns in Northern Ireland.

A dash — denotes no cases; a blank space denotes disease not notifiable or no return available.

* Measles and whooping-cough are not notifiable in Scotland, and the returns are therefore an approximation only.

† Includes primary form for England and Wales, London (administrative county), and Northern Ireland.

‡ Includes puerperal fever for England and Wales and Eire.

§ Owing to movements of population, birth and death rates for Northern Ireland are still not available.

buy what medical workers have thus built up, a Government would not be at the same time depriving the public of the right to choose its own doctor in its own way, and at a cost which ultimately may be far greater for the community as a whole than it is at present.

These are but some aspects of a question which is far less simple than it appears at a first and summary inspection. It is not a question which can be answered easily one way or the other; but it is one which should be considered calmly and realistically. Any decision of the Government will be a first step in a certain direction, and in making up their minds about the matter medical men should be clear what this direction is and whether they want to follow it.

CAMPAIGN AGAINST RHEUMATISM

The publication by the Department of Health for Scotland of the report of its Medical Advisory Committee on the chronic rheumatic diseases is an important event in the solution of this great social problem. As long ago as 1927 the Ministry of Health indicated that rheumatic disease accounted for nearly one-sixth of the industrial invalidity in England. Rheumatism will bulk largely in Social Insurance, since a big section of the population, the dependants, and especially the housewives, mainly untouched by the National Health Insurance Acts, will come within the scheme now being drafted by the Government. The incidence of chronic articular rheumatism in female domestic workers is disproportionately high.

The Scottish report gives an account of the incidence, some of the aetiological factors, and existing facilities for treatment. A subcommittee under the chairmanship of Sir John Fraser was appointed to "consider what action can be devised for the treatment of chronic rheumatism among the general population," and it is in the findings of this subcommittee that the chief interest of the report lies; a fairly full abstract appeared in the *Journal* of Oct. 6. The scheme is to be based on the medical schools and teaching hospitals, in which small units of 20 to 40 beds would provide opportunities for research into pathology and diagnosis and would test the efficacy of methods of treatment under controlled conditions. To these would be linked large hospital units, situated at a convenient distance, for the long-term treatment of suitable cases. To ensure continuity, both would be directed by the same staff of physicians and surgeons experienced in these diseases, but the report wisely stresses that the subject should not be divorced from general medicine by the creation of a narrow specialty. Close co-operation between physicians and orthopaedic surgeons will be of the highest importance in any scheme, on lines now being discussed by a joint committee of the British Orthopaedic Association and the Empire Rheumatism Council. The units will provide for training medical students—an important provision when it is remembered how much of the practising doctor's time is spent in the management of rheumatic diseases. Postgraduate classes will also make the general practitioner familiar with modern advances in diagnosis and treatment.

While the scheme of hospital units thus foreshadowed will do much for the treatment of such serious conditions as rheumatoid arthritis, it must not be forgotten that many patients, especially housewives, cannot leave their homes for a long period of treatment in hospital. There are also many cases of minor rheumatic disorders, particularly muscular rheumatism, for which hospital treatment is unnecessary. If industrial invalidity from rheumatism is to be reduced the family doctor must be supported in his efforts by the provision of facilities for laboratory investigation and physiotherapy, and, not least, for consultation with physicians experienced in the disease. It is in the neglect or superficial treatment of cases which appear trivial at first that the seeds of permanent crippling are sown, and at this stage the family doctor has the opportunity and the responsibility of providing prompt and effective treatment. To help him the Scottish report suggests "peripheral clinics" starting on modest lines and linked with the central hospital and with orthopaedic services. But perhaps such clinics should be provided first and quickly in order to deal on the largest possible scale with rheumatism in its early stages: this could be done at small expense in the smaller hospitals and district or cottage hospitals. Periodical visits of consultants and the provision of means for simple physiotherapy would be of much value. Cases in need of more elaborate treatment could be transferred to more fully equipped centres. If hospital accommodation for "long-term" treatment is not to be overloaded patients who have made enough progress might be transferred to a convalescent station where they could reside in hostels linked with a physiotherapy unit; rehabilitation, occupational therapy, and recreation should be available under medical observation. Such stations would also be of value for giving rest and recreation to the overworked. "Preventive rehabilitation" would save many a worker from the accident and the injury that finally compel him to give up his work temporarily.

The Scottish report stresses a point in physiotherapy too often overlooked—the need as early as possible to replace passive treatment by active exercise, such as is provided by occupational therapy and rehabilitation. Routine—and sometimes perfunctory—treatment prolonged at a physiotherapy centre may induce a hypochondriasis. However skilled the physiotherapist, the effect of treatment must be assessed periodically by the physician or surgeon in charge of the case. Physiotherapy should be based on a clear conception of the pathology of the condition to be treated, and the masseur cannot be expected to appreciate this. Students should be instructed in the technique of physical methods of treatment, for harm may result if they are applied mechanically. Sir Robert Jones once said, "Never massage the knee-joints"—a dogmatic utterance perhaps, but with much wisdom in it. Ill-advised massage has turned many an early villous synovitis into a chronically creaking knee.

The Scottish report should be studied in conjunction with a report by Dr. W. S. C. Copeman[1] on the treatment of rheumatism in Sweden, where this has been a national concern for many years and where much experience of hospital treatment has been gained.

Medical News

Dr. W. E. Chiesman has been appointed Treasury medical adviser on the retirement of Sir Henry Bashford on Dec. 6.

A conference of the Hospital Contributory Schemes Administrators Association will be held at the Royal College of Nursing, Henrietta Place, Cavendish Square, W., to-day (Saturday, Nov. 24,) at 2 o'clock. Mr. H. E. Griffiths, chairman of the executive committee of the British Council for Rehabilitation, and honorary consulting surgeon to the Ministry of Supply, will give an address and show the film, "Rehabilitation in a Royal Ordnance Factory."

The National Association for the Prevention of Tuberculosis has arranged a discussion on "Can the tuberculous be trained in industrial design, arts and crafts?" to be held in the Hastings Hall of B.M.A. House, Tavistock Square, W.C., on Thursday, Nov. 29, at 2.30 p.m., with the Duchess of Portland in the chair. The speakers include Sir William Crawford, Mr. Philip James, director of the Council of Arts, Mr. H. W. Yoxall, and Dr. W. C. Fowler. Admission by ticket only, from the N.A.P.T., Tavistock House North, Tavistock Square, London, W.C.1.

The British Institute of Philosophy (University Hall, 14, Gordon Square, W.C.1) has issued a programme of lectures to be given during the Michaelmas and Lent terms. The course includes a lecture on Nov. 29 by Prof. H. Dingle on "Main Problems of Natural Philosophy"; and the Manson Lecture on Dec. 14 by Dr. W. Russell Brain on "The Neurological Approach to the Problem of Perception." All the lectures may be attended by members of the general public free of charge, on application to the Director of Studies at the address given above.

A Conference on "Homes and Hostels of the Future" arranged by the National Council for the Unmarried Mother and her Child will be held in the Queen Mary Hall, Y.W.C.A. Central Club, Great Russell Street, W.C.1, on Thursday, Nov. 29, at 10 a.m. The speakers include Dr. Dorothy Taylor, Dr. John Fenton, Dr. Letitia Fairfield, and Lieut.-Col. Albertine Winner. Tickets (2s. 6d.) may be had from the general secretary, N.C.U.M.C., 117, Piccadilly, W.1.

Sir Henry Dale, M.D., P.R.S., will deliver a series of three lectures on "Recent Developments in Chemical Therapeutics" before the Royal Institution (21, Albemarle Street, W.) on Tuesdays, Dec. 4, 11, and 18, at 5.15 p.m. In the first lecture he will discuss "The Beginning: Dyes, Arsenicals, Antimonials, etc."; in the second "Sulphanilamide and its Derivatives"; and in the third "Penicillin and Other Antibiotics."

There will be a clinical meeting of the Medical Society of the L.C.C. Service at Lambeth Hospital, Brook Drive, S.E., on Thursday, Dec 6, at 3 p.m., when members of the staffs of Lambeth and St. Giles' Hospitals will demonstrate cases.

The Chelsea Clinical Society has arranged a reopening dinner meeting, to be held under the presidency of Dr. Desmond McManus, at 6.30 for 7 p.m. on Tuesday, Dec. 11, at the South Kensington Hotel, Queen's Gate Terrace. All members who would wish to attend are asked to signify their intention to the secretary—Mr. A. Rugg-Gunn, 18, Harley Street, W.—and are asked to restrict their guests to those who may be regarded as potential members.

The following promotions have been made in the London County Council's mental health services: Dr. A. B. Stokes to be medical superintendent of the Maudsley Hospital, Denmark Hill, S.E.; Dr. A. C. Dalzell to be medical superintendent of Friern Hospital, New Southgate, N.; Dr. J. F. MacMahon to be medical superintendent of The Manor, Epsom.

There are many nursing orderlies who on release from the Royal Air Force are desirous of continuing their association with the medical and dental professions. Many could be suitably employed as secretaries, receptionists, and secretary-attendants to private consultants, medical practitioners, and dental surgeons. A register of such personnel is held by the Commandant, Medical Training Depot and Establishment, Royal Air Force Station, Halton, to whom applications may be made.

A Save the Children Fund relief unit has been assembled in London ready for departure for Malaya; its medical officer is Dr. R. W. Ross, who has seen service in tropical waters with the Navy.

Lieut.-Col. F. L. McLaughlin, M.D., has been appointed neuropsychiatrist to the British Ministry of Pensions and to St. Vincent's Hospital, Dublin.

American ambulances used in this country through the war years are being distributed to hospitals. On Nov. 12 the first of them was received by the General Infirmary at Leeds. Another ambulance was sent to Bradford, and a third to York.

Letters, Notes, and Answers

All communications with regard to editorial business should be addressed to THE EDITOR, BRITISH MEDICAL JOURNAL, B.M.A. HOUSE, TAVISTOCK SQUARE, LONDON, W.C.1. TELEPHONE: EUSTON 2111. TELEGRAMS: *Aitiology Westcent, London.* ORIGINAL ARTICLES AND LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated.

Authors desiring REPRINTS should communicate with the Publishing Manager, B.M.A. House, Tavistock Square, W.C.1, on receipt of proofs. Authors over-seas should indicate on MSS. if reprints are required, as proofs are not sent abroad.

ADVERTISEMENTS should be addressed to the Advertisement Manager, B.M.A. House, Tavistock Square, London, W.C.1 (hours 9 a.m. to 5 p.m.). TELEPHONE: EUSTON 2111. TELEGRAMS: *Articulate Westcent, London.*

MEMBERS' SUBSCRIPTIONS should be sent to the SECRETARY of the Association. TELEPHONE: EUSTON 2111. TELEGRAMS: *Medisecra Westcent, London.*

B.M.A. SCOTTISH OFFICE: 7, Drumsheugh Gardens, Edinburgh.

ANY QUESTIONS?

Rorschach Test

Q.—*Could you tell me briefly what the Rorschach test is and what objective information it is likely to yield? Could it, for example, establish a suspected diagnosis of psychoneurosis? I know that the method can be used only by somebody trained in it, but would also like to know whether it is widely used by British psychiatrists.*

A.—The Rorschach test consists of a series of symmetrical patterns such as are made by folding paper over a large irregular ink-blot. The Rorschach patterns were originally made in this way, and subsequently photographed and printed. The patterns are shown to the subject, and he is asked to "see" in them any figures he can imagine. Intellectual capacity is shown by the ability to organize the whole, or large parts, of the ink-blot into a single figure which has at the same time a convincing quality. Schizophrenia may be indicated by the appearance of bizarre and unlikely figures. Hypochondriasis may show itself in the recurrence of anatomical images, etc. In the hands of the skilled interpreter the test can give reliable and valuable information on normal and abnormal traits; it would certainly be possible to make a reasonably sure diagnosis of psychoneurosis on the basis of the test alone. Despite the high repute the test enjoys, it is used by only very few British psychiatrists; it takes a long time to administer and interpret, and both training and experience are required of the interpreter.

Incidence of Types of Dysentery

Q.—*What has been the relative incidence of the different types of dysentery in the British Isles during the last few years?*

A.—The notifications published by the Registrar-General are not tabulated by the type of dysentery. An approximation of the various types can be obtained from the returns of the E.P.H.L.S. The following distribution was obtained from these returns:

Type	Per 1,000 Total Cases
Sonne	892
Flexner	75
Newcastle	28
Amoebic	3
Schmitz	0.4
Shiga	2

Caution must be used in drawing any inferences from these values. The returns of the E.P.H.L.S. cannot be taken as representative, since they do not cover the whole country; some areas are almost completely covered and some are not included. Also the returns include cases from the Services. These military cases probably have a different distribution of types from that in the general population.

Inheritance of Retinitis Pigmentosa

Q.—*A man suffering from retinitis pigmentosa has hitherto refrained from having a child because of the fear that it too might suffer from this horrible disease. He and his wife want to know what risk is involved. If it is too great they will adopt a baby. One of the patient's sisters is similarly affected, but apart from this his father and mother, and, so far as he knows, all other relatives, are normal.*

A.—Retinitis pigmentosa may be due to any one of several genes (some of them partially sex-linked, though that is not of practical importance in the present connexion). Dominant inheritance is ruled out by the history given, and in any event is exceedingly rare. Sex-linked transmission is also rare, and is ruled out by the sex of the affected sib. The great bulk of instances of retinitis pigmentosa are due to a recessive gene. The affected sib and the normality of all other relatives leave no reasonable doubt that this is the mode of transmission in the present instance. The patient must pass on the gene for the condition; but only if his wife happens to be a carrier can a child receive the requisite double dose and so be

MEDICAL WAR RELIEF

On another page readers will find an appeal from the chairman and honorary treasurer of the Medical War Relief Fund—the second only that the Fund has made—for the generous support of all doctors in the work which the Fund has set itself to do, but which, with problems of demobilization and resettlement, will in the coming year be far beyond its resources. There is little to add to that appeal except a hint that this is not the occasion for the half-guinea or guinea donation with which one is apt to respond to calls upon the purse but for a sum which represents a real sacrifice, even as those who need help have sacrificed in the war. The appeal is for £100,000 and is being made to doctors only. This is not too high a target for any large profession which is zealous for the welfare of its members, still less so in the case of the medical profession, which has always been anxious to help its own. This figure, however, can be reached only if donations are sent in the manner and spirit of the 73 individual subscriptions which, within a fortnight of opening the appeal, brought in a total of £1,672. They should be sent as soon as possible to the honorary treasurer of the Medical War Relief Fund, at B.M.A. House, Tavistock Square, London, W.C.1.

THYROID AND SEX FUNCTION

Thyroid extract is often used clinically in treating sex disorders in women, though the rationale of this is not clear. We know little more than that the thyroid gland has some connexion with sex, since disturbances in sex function accompany thyroid disease. On the experimental side Engle[1] has recently established that thyroid deficiency in monkeys results in amenorrhoea, and that a course of thyroid treatment given for 10 days (20–60 mg. of thyroid substance daily) brings on menstrual bleeding 1–19 days after the last administration, followed by one or two further bleedings at normal cyclic intervals, even though there had been as many as 200 days of amenorrhoea preceding the treatment. True menstrual bleeding is not the only form of bleeding inhibited in the hypothyroid monkeys. They do not bleed after spaying as normal monkeys do, and after they are spayed the usual method of producing oestrogen-withdrawal bleeding (40 μg. of oestradiol benzoate daily for 10 days) is ineffective; but when thyroid is given as well the usual reaction follows. These experiments clearly demonstrate that thyroid has some role in the menstrual cycle, but give little indication of its mode of action.

Chu[2] has made a close study of the relation between thyroid and gonads: he has shown that thyroidectomy in the rabbit is followed by an increase in the number of follicles in the ovary and a decrease in the luteinizing potency of the pituitary gland. It is assumed that the thyroid stimulates the secretion of follicle-stimulating gonadotrophin and depresses the secretion of luteinizer. In Chu's experiments the reduction in luteinizing power was so great that mating did not produce ovulation in thyroidectomized rabbits, though the ovaries were extra-sensitive to injections of chorionic gonadotrophin. The normal ovulation response to mating could be restored by administering thyroid. The stimulation of the follicles after thyroidectomy should produce an increase in secretion of oestrogen. This extra oestrogen may explain the fact that Chu[3] was later able to show that thyroidectomy during pregnancy in the rabbit led to the resorption of embryos or the premature birth of dead foetuses. Pregnancy induced in thyroidectomized rabbits by mating and injection of chorionic gonadotrophin is usually longer than normal and also results in stillborn litters. The interpretation of this result is, however, complicated by superfecundation, since the extra follicles in the thyroidectomized rabbits respond to the ovulating injection of chorionic gonadotrophin, and at mid-term as many as 22 embryos may be present. Chu was successful in some cases in maintaining normal pregnancy in thyroidectomized rabbits treated with thyroid; ovulation was produced by mating in these animals.

If the activated follicles do produce excess oestrogen, however, it is difficult to see why they persist, since it is generally accepted that excess oestrogen inhibits the production or secretion of follicle-stimulating gonadotrophin. Investigating this point, Chu and Lee[4] find that the ovarian inhibition caused by large doses of oestrogen in intact rabbits does not occur in thyroidectomized rabbits. The follicular hypertrophy produced by thyroidectomy may be inhibited by thyroid treatment, and if the doses of thyroid are large the ovary may even become atrophic. Subthreshold doses of oestrogen insufficient to inhibit ovarian activity in intact rabbits were effective when given with thyroid, and administration of thyroid increased the ovulating activity of the rabbit hypophysis. These and other results lead the authors to conclude that thyroid secretions inhibit the secretion of follicle-stimulating gonadotrophin and stimulate the secretion of luteinizing hormone. It also appears that the effects of oestrogen on the follicle-stimulating activity of the pituitary are not direct and are either mediated by the thyroid or potentiated by thyroid secretion.

If these findings are confirmed there is little doubt that more account must be taken of the part played by the thyroid gland in the regulation of sex function. But at the moment the picture is by no means clear.

SOME CAUSES OF SYNCOPE

Fainting or syncope is a common enough occurrence, but it has many possible causes. A study of these is the basis of a recent article by Engel, Ferris, and Romano.[5] Some causes are rare, but their possibility must be borne in mind. The ultimate reason for the loss of consciousness is cerebral anaemia. The two contributory causes of this are fall in blood pressure and diminished output of blood from the heart. Failure of return of blood to the heart, due to pooling, loss of vasomotor tone, fall in rate, contributes to these defects. In the majority of cases the diagnosis can be made with a fair degree of certainty by clinical means alone if the patient is seen at the time; a careful history of the circumstances of the attack and of any premonitory symptoms may even provide a diagnosis in retrospect. The commonest group is that in which fainting results from a fall in blood pressure, which the authors call the vaso-depressor type. This includes what is more commonly known as the vaso-vagal faint. The relative importance of the vagal factor varies. In very sudden faints it may predominate, as Lewis pointed out long ago. In others the onset is more gradual and the vasomotor side is dominant; such cases may be purely psychological in origin. Sometimes a depressor reflex from the carotid sinus is over-active. This carotid sinus syndrome has attracted much attention, but in all probability it is rare, although a sensitive carotid sinus is not uncommon in the elderly. An interesting, though rare, type is true orthostatic hypotension; here there seems to be no control over the distribution of the blood in relation to posture. Possibly some lesion of the central nervous system lies behind it, or of the sympathetic. It can be caused artificially by very extensive affected. The chance of her being a carrier is remote—hundreds to one against—so the chance of a baby's being affected is very small indeed.

[2] *Endocrinology*, 1944, **34**, 90.

[3] *J. Endocrinol.*, 1945, **4**, 109.

[4] *J. Endocrinol.*, 1945, **4**, 115.

[5] *Cincinn. J. Med.*, 1945, **26**, 93.

The case would be entirely altered if the husband and wife were blood relatives. If, for example, they were first cousins she would stand a one-in-four chance of being a carrier, with a one-in-eight probability that any child would be affected.

One possibility should be mentioned, though only to be discussed. Could the affected persons in the present generation owe their abnormality to a dominant mutation and so pass it on to half their offspring? Even apart from the fact that there are two of them, the odds are many thousands to one against.

An important point of principle remains. Any child will receive the recessive gene from the father and so must inevitably be a carrier. Is it right to perpetuate the gene, with the chance that in some future generation it may meet its like and a sibship with retinitis pigmentosa appear once again? In my view this is not a sufficient reason for refraining from parenthood. If all of us but knew what undesirable recessives we carried, and adopted so conscientious an attitude towards posterity, the birth rate would indeed show a catastrophic decline.

This couple can therefore be told (unless they are cousins) that the risk is very small—only one in some hundreds. They should take that risk and have their own child.

The Law and Sterilization

Q.—*A woman aged 35 has had nine children, whose ages range from 15 years to 8 months. She is anxious to have no more pregnancies, but various methods of birth control have been unsuccessful. She is in hospital now for a colpoperineorrhaphy for a moderate degree of prolapse and complains also of backache, pains in the groins, and some epimenorrhagia. She and her husband are constantly asking for a sterilizing operation to be performed. Is this ethically right or justifiable? What are the chief considerations to be borne in mind when patients insistently request sterilization?*

A.—Ethically, the doctor's first duty is to do his best to preserve the patient's life and health. If legal considerations are laid aside, he is justified in sterilizing if he is satisfied that it is the best course in the patient's interest, though doubtless he will feel he owes a duty to obtain the husband's consent if possible. There is no reason to suppose that this ethical principle conflicts in any way with the law of the land.

A citizen of this country may do anything that is not forbidden by law. No statute, nor any reported decision of a judge, forbids a doctor to sterilize a woman with her consent. The only remaining possibility is that to do so offends against some hitherto unformulated principle of common law, and is therefore either an offence against the State or a wrong against some individual. If a doctor were prosecuted for sterilizing with the woman's consent—and the police would hesitate a long time before such an innovation—a court would have power to declare the common law infringed, but might well take the view that, as Parliament had already had plenty of opportunity to declare the law of offences against the person, the courts should presume that the existing statutes fully stated that law and that judges should not now create new offences in it.

If sterilization with consent is not a criminal offence, the only person who could conceivably be wronged by it is the husband. If he consented he would have no right of action. Even if he did not, it is highly doubtful whether a court would hold that he had a right to damages. If the medical reasons were sound the court would be most unlikely to say he had the right to refuse consent against the interests of his wife's health. (See also a question and answer headed "Voluntary Sterilization and the Law" in the *Journal* of Nov. 27, 1943, p. 701.)

Calcium *o*-Iodoxybenzoate in Rheumatism

Q.—*Can you give me information about the use of calcium o-iodoxybenzoate in spondylitis and rheumatism of the hip-joints? Has experience shown it to have beneficial results in these conditions, and is there any chance of constitutional upsets apart from gastric disturbances?*

A.—Without fuller details of the case it is hardly possible to reply to this question. What is the age of the patient? Is the condition in an active stage or is it chronic? Is any cause known? From the association of spondylitis with arthritis of the hip, and assuming that the patient is young, it seems likely to be a case of ankylosing spondylitis, in which disease the hip-joints are affected very soon after the spine in most cases. If, on the other hand, the patient is over middle age the condition is probably osteo-arthritis affecting both spine and hip-joints—a disease differing entirely in pathology, aetiology, prognosis, and treatment. In the absence of fuller information it can only be said that in the writer's experience calcium *o*-iodoxybenzoate is useless in ankylosing spondylitis; in other conditions it often relieves pain; and where there is associated fibrositis, as is often the case, some amelioration of symptoms is frequently experienced. The writer has not met with any constitutional disturbance accompanying its use beyond occasional gastric upset.

Discharge Swabs in Diphtheria

Q.—*I understand a few fever hospitals have dispensed with discharge swabs for diphtheria cases. Is there sufficient evidence to show whether this procedure will raise the incidence of diphtheria locally? What is the modern teaching on this question?*

A.—Standards of bacteriological clearance after diphtheria have varied quite widely without affecting return-case rates. Fever hospital administrators tend to resist repeated and meticulous swabbing of convalescent cases, partly for this reason but also because it defeats its own end by prolonging hospitalization and thereby increasing the risk of reinfection, particularly under open-ward conditions. This question of avoiding ward cross-infections should never be dissociated from the problem of the convalescent diphtheria carrier. Given adequate protection of the child from this point of view, and assuming the presence of healthy mucous membranes, a commonly accepted standard of bacteriological clearance is two swabs taken at an interval of a few days. Because it gives a more clear-cut picture, tellurite medium is for this purpose usually preferred to Loeffler's.

Penicillin in Meningitis

Q.—*What is the consensus as to the merits of intrathecal penicillin in meningitis (i.e., pneumococcal)? Hoyne of Chicago and Abel and Firor of Johns Hopkins say that intrathecal treatment is unphysiological. Is this true? Rosenberg and Sylvester ("Science," Aug. 11, 1944, p. 132) state that intravenous or intramuscular injection of 20,000 to 40,000 units of penicillin yields a cerebrospinal fluid concentration of 0.03 to 0.05 unit per c.cm. in 60 to 140 minutes, and that this is an adequate concentration to control meningitis. Is this true? Is the pleocytosis caused by intrathecal penicillin important?*

A.—There is abundant evidence that in order to maintain an adequate concentration of penicillin in the cerebrospinal fluid intrathecal injection is necessary. The amount passing into it after intramuscular or intravenous injection is too small, although there is some evidence that when the meninges are inflamed this increases somewhat. A concentration of 0.03 to 0.05 unit per c.cm. is only just enough to inhibit the growth of a sensitive organism; after intrathecal injection ten times this amount may still be present after 24 hours. The questioner is referred to the paper by Cairns and others (*Lancet*, 1944, **1**, 655) for a full account of the rationale, technique, and results of intrathecal penicillin treatment for pneumococcal meningitis.

The meningeal irritation caused by impure penicillin is naturally undesirable, although it is certainly not a contraindication to the treatment if no better penicillin is available. Penicillin of good quality (i.e., of over 500 units per mg.) has not this disadvantage. M. E. Florey and N. G. Heatley (*Lancet*, 1945, **1**, 748) have even suggested that if highly purified penicillin is available a sufficient dose could be given intrathecally to exert a systemic effect for 12 hours, as well as a local one. Patients requiring both forms of treatment could then be left undisturbed at night instead of continuing to receive three-hourly intramuscular injections.

Exertion Urticaria

Q.—*A healthy athletic man of 42 years has suffered since childhood from undue sensitiveness to salt. After bathing in the sea he becomes covered in small blisters. The same happens when he perspires freely. He eats a normal amount of salt. Is this a common condition? I have advised smearing the skin with an oil preparation.*

A.—Is there any evidence that this patient is sensitive to salt? The condition described here is almost certainly an exposure and exertion urticaria—a rare condition which usually starts about puberty and may persist a variable number of years or for life. It is clearly the result of an idiosyncrasy to some metabolic activities consequent upon exposure and exertion, with alteration in capillary permeability (upon which a good deal of work has been done by physiologists); treatment is not effective. I do not think the application of oil will alter the position.

Allergic Disease in a Family

Q.—*Please advise on the modern approach to treatment of a family of three generations severely affected by "allergic" conditions—e.g., asthma, hay-fever, eczema, and vasomotor rhinitis. Is there a general approach, apart from specific desensitization?*

A.—Investigations such as those of R. S. B. Pearson (*Quart. J. Med.*, 1937, **30**, 165) indicate that protein sensitivity is not infrequently found in subjects with no history of asthma or allergy, and suggest that something else is necessary for the appearance of symptoms. The common observation that allergic manifestations may disappear when a patient is admitted to hospital, even though contact with the allergen is maintained, emphasizes the importance of inhibitory factors in preventing the appearance of these disorders. Many psychologists have suggested that allergic affections are often a familial neurosis, provoked by the example or the anxiety of the sympathectomy. Complete cardiac standstill provides another cause. This may be reflex and provoked by stimulation of the carotid sinus. The standstill may affect only the ventricles, the auricles continuing to beat. These cases provide the Stokes-Adams syndrome. Many are due to failure in auriculo-ventricular conduction; but records, rarely obtainable, have shown that in others ventricular fibrillation or ventricular tachycardia is present.[6] In a unique case described by Bruce Pearson[7] there were prolonged complete cardiac standstill and profound bradycardia quite unaffected by atropine or anything else. Possibly, in this instance, the sinus was in a state of diminished excitability.

Occasionally fainting results from over-ventilation of the lungs. These patients are closely linked with those in whom hysterical fainting occurs. There is no change in the pulse rate, in colour, or in blood pressure; nor does the encephalogram show the change to high-voltage deflections which are constantly recorded in true syncope, thus differentiating hysterical "fainting" from any real circulatory disturbance. In old people syncope may be prolonged and recovery slow, perhaps because of cerebral arteriosclerosis. The only valvular lesion with which syncope is at all common is aortic stenosis, and that the type occurring in the elderly—fibro-calcareous stenosis.

The authors stress the following points in the history: frequency of faints, posture, nature of provocative stimulus, duration, focal neurological symptoms, rate of recovery, biting of tongue, or incontinence of sphincters; changes in colour, convulsive movements, sweating, changes in pulse and blood-pressure; and physical examination of the heart. Information on these points will usually provide a diagnosis. This is important, for fainting is always an alarming event for laymen and tends to arouse serious doubts as to the state of the heart. It will be seen that most cases are not serious in nature, but that a small minority are.

INTELLIGENCE AND EPILEPSY

The development of epilepsy in a previously healthy and intelligent child raises many grave problems for both parents and doctors. Among them is the question of education. Is it worth while for the child to embark upon a public school or university career, and is some measure of intellectual deterioration and impairment of memory to be anticipated or not? From a follow-up study made by Himler and Raphael[8] of 93 epileptic undergraduates at the University of Michigan it seems clear that the presence of seizures in individuals within the higher intelligence group need not necessarily constitute a barrier to academic training. Nor should it debar successful personal, social, and vocational adjustment after leaving college. Of the 93 students, 63 (70%) secured fair or satisfactory academic grades, while only 22 (24%) were classed as unsatisfactory. The proportion of these students who graduated, or whose continuance at college gave promise, was from 65 to 70%. Graduates included three with medical degrees, six with law degrees, and eight with masters' degrees. The authors also found that the seizures in college students generally ran a relatively benign course and responded favourably to treatment.

Yet another favourable conclusion can be drawn from a study of 186 normal and epileptic twins by Lennox and Collins.[9] Their data showed that with a good mental inheritance an epileptic patient is able to maintain a normal level of intelligence so long as there is no underlying gross lesion of the brain—for example, injury or encephalitis. In other words, contrary to common medical belief, a normally intelligent person who develops idiopathic epilepsy is much less likely to deteriorate mentally than one who develops symptomatic epilepsy.

ACTION OF CAFFEINE IN FATIGUE

Most of us assume that the action of caffeine in relieving fatigue is an action on the brain, for it is known to increase the speed at which work requiring mental concentration can be done. Recently, however, A. C. Ivy and his colleagues[1] showed that in man caffeine increases the capacity for muscular work in subjects unfatigued, and also the rate at which the muscles recover from fatigue. These observations suggested that caffeine might have a peripheral action on skeletal muscle as well as a central action; this would add but one more to the many pharmacological actions of caffeine, which affects not only the brain but also the heart, the kidneys, and the bronchioles. Huidobro and Amenbar,[2] working in Santiago, have shown that caffeine has such an action. If in the anaesthetized cat the nerve to the quadriceps is stimulated—for example, 14 times in 10 seconds—the muscle gives a succession of regular contractions; when an injection of 10 mg. caffeine is made into the femoral artery the contraction increases by 25%. Huidobro and Amenbar also found that caffeine intensified the action of prostigmin on muscle, and antagonized the action of curare, though the antagonism was brief. The relation between caffeine on the one hand and prostigmin and curare on the other indicated that caffeine might modify the action of acetylcholine on skeletal muscle.

It is now generally recognized that the motor nerve transmits its impulse to the muscle chemically by the release of acetylcholine. Experiment showed the indication to be correct, for caffeine increased the contraction produced in skeletal muscle by the intra-arterial injection of acetylcholine. Huidobro and Amenbar proceeded to examine the action of caffeine on the sympathetic ganglion, for here also the transmission of an impulse from the preganglionic to the postganglionic fibre is due to the liberation of acetylcholine. They determined the size of the response of the cat's nictitating membrane to a succession of injections of acetylcholine into the artery leading to the superior cervical ganglion, and showed that the interposition of an injection of caffeine increased the size of the response. These workers have therefore reached two interesting conclusions. They have shown that caffeine has a direct peripheral action on muscle by which the size of the muscle response to a given stimulus is increased. It is not clear that this effect is greater in fatigued muscle than in unfatigued muscle, but it is definite in both. Probably a liberal allowance of coffee or tea will benefit those suffering from myasthenia gravis. Certainly a cup of coffee is the right preliminary when we wish to try our strength at a fair. The second conclusion is that caffeine augments the action of acetylcholine not only in skeletal muscle but also in sympathetic ganglia; this should lead to a general investigation which may reveal that the same augmentation occurs in all organs where acetylcholine exerts an action. This would illuminate both the action of caffeine and the functions of acetylcholine, which is being seen to play an ever-increasing part in body processes.

Lieut.-Col. Gordon King, R.A.M.C., sends the gratifying news that the B.M.A. library in Hong Kong was found to be almost intact, and it has been temporarily stored in the University Library. The library is the only part of the university which escaped destruction and looting.

parents. Nevertheless, it is a great deal easier to theorize about allergy than to cure it, and, while there can be no doubt that inhibitory forces exist within the organism which can check the appearance of allergy in an individual who has inherited the tendency, there is no evidence that we can direct these forces in such a way, for example, as to prevent the appearance of infantile eczema in the offspring of allergic parents. It may therefore be most practical in the long run to concentrate on the factor of protein sensitization and try to render the home environment free from the common allergens—dusts and moulds.

Unsightly Bursa

Q.—*Is there any curative treatment for the pads of fat or bursae which appear round the external malleoli of middle-aged women? They are not painful but very unsightly.*

A.—Treatment for this condition can be only by deep massage and elastic bandaging. There is no other satisfactory palliative measure. Curative treatment by plastic operations seems desirable only where the cosmetic result is of particular importance.

Carbachol for Migraine

Q.—*Has carbachol any effect on migraine? If so, what doses should be used?*

A.—Carbachol has been stated to have an effect in migraine by A. K. James in an article in this *Journal* (May 12, 1945, p. 663). He found that a patient to whom he was giving tablets of carbachol orally for a dilated colon suffered much less from attacks of migraine during the course of the treatment. He therefore tried the method in other patients, and has published results in 12. . He recommends tablets each containing 0.002 g. (which is 2 mg. or 1/30 grain); two of these tablets are taken at once, and this dose is repeated two or three times a day. The daily dose was mostly 6 mg., but one patient was given 12 mg.

Colloidal Gold (Lange) Reaction

Q.—*Can you explain why it is that in an early case of G.P.I. the cerebrospinal fluid, which is W.R.-positive and gives a marked paretic reaction with Lange's gold test, will, after being kept frozen for three weeks, give a characteristic luetic curve? I have seen this twice recently. Is it common?*

A.—The colloidal gold (Lange) reaction is dependent on the presence of globulins in the cerebrospinal fluid; freezing the fluid in the refrigerator tends to "denature" the globulins and render them less soluble when the fluid is thawed. In the case of a fluid which has been frozen and then thawed this might explain the change in the gold curve. The difficulty could probably be overcome by drying the cerebrospinal fluid in the same way as serum is dried; this process apparently does not denature the globulins.

Miller-Abbott Tube

Q.—*How is the Miller-Abbott tube used and what are the indications for employing it?*

A.—The Miller-Abbott tube is a double-channelled narrow-bore rubber tube which is used for the relief of obstruction of the small bowel. In some cases it also helps to locate the site of obstruction. One channel is larger than the other and is used for sucking out the contents of the stomach and intestine; the smaller channel is used for the purpose of injecting air into a rubber balloon which surrounds the distal end.

The tube should be used only for those cases of obstruction in which one can fairly exclude strangulation of the bowel, for emptying the bowel above the strangled coil will in nowise prevent supervention of gangrene. Its chief use is in cases of obstruction due to kinks and adhesions in which distension actually increases the obstruction, in cases of paralytic ileus, and perhaps in some cases of incomplete obturation—e.g., obstruction by a gall-stone.

The tube can be introduced through the mouth or nose—preferably through the nostril, which has the clearest passage. If necessary the nostril and pharynx may be sprayed with a solution of cocaine to lessen irritation. The tube is moistened and pushed gently through the nostril till it reaches the nasopharynx; the patient is then given a little water to swallow while the tube is pushed on towards the gullet. Thereafter it is carried down to the stomach by the patient's own swallowing efforts. The fact that the tube has reached the stomach may be told either by the length of tube which has been swallowed, by the nature and quantity of fluid which may be aspirated, or by inflating the little balloon and gently drawing the tube back till the balloon is stopped by the cardia. After relieving the distended stomach by aspiration of the contents the patient is told to lie on the right side with a view to encouraging the tube to pass on to the duodenum. This should take place within ten or fifteen minutes. The fact that the tube is within the duodenum can sometimes be ascertained by noting the nature and reaction of the aspirated contents; otherwise by inflating the balloon with about 30 c.cm. of air and noting the rather irregular resistance met with during inflation. When once within the small bowel, the tube with its inflated end is gradually forced along the lumen. From time to time the contents of the bowel are aspirated through the larger channel so that the bowel is emptied of air and fluid as the tube advances. Its rate of advance varies from one to two feet an hour. Ultimately the end of the tube will reach down to the site of obstruction, and the relief of distension may actually cure the condition. In cases of organic stricture the tube will stop on the proximal side of the obstruction, and either may be seen by *x*-ray screening, or a little barium emulsion may be injected through the tube and may serve to demonstrate the obstruction.

The caution must be repeated that the use of the Miller-Abbott tube will not prevent gangrene in a strangled coil of gut; in such cases it may relieve the distension of the bowel above the obstruction and so make the necessary operation more safe.

LETTERS, NOTES, ETC.

Venereology

Mr. L. E. Eyres, M.A., writes from Ampleforth College, York: May a schoolmaster, with some knowledge of Latin and Greek, but none of medicine, intervene in your interesting debate on venereology, and offer the following reflections? The difficulty is enhanced by the fact that "V.D." is a violent euphemism. In itself "venereal" merely means "pertaining to the goddess of Love," and the emotion which a man feels towards the harlot who gives him gonorrhoea is certainly not *love,* or anything like it. In a world where spades were spades V.D. would mean, at worst, nymphomania, or its masculine counterpart. And when V.D. is shortened to "venereal" it becomes doubly euphemistic. The nuisance about euphemisms is that once they become established they deny us the use of the word or phrase in its proper sense. If I say "my mother went home yesterday" there are some tiresome people who will take me to mean that she died yesterday. Nor can I say that I have found a comfortable asylum for Aunt Susan without implying that she is insane. With a small *v* "venus" means beauty, charm, etc. Yet if I call Miss Smith a venereal young woman she will not take it as the compliment that it is, though she will not mind my calling her fiancé a *martial* young man. The expression "V.D." is now firmly established, and, though it is a slander on Aphrodite, pedants must acquiesce in it. But to introduce a *twofold* euphemism and call it simply "venereal" would be regrettable, I think, in a scientific treatise. Aedoeology would be strictly accurate: it is a pity that it is such a hideous word. But is it really any worse than, say, gynaecology or aitiology?

War-blinded Men

From St. Dunstan's (9-11, Park Crescent, W.1) there comes an illustrated pamphlet with an article by Sir Ian Fraser, chairman of the Executive Council, describing the work which that institution, a product of the earlier war, has done during the war just ended. Work for the blinded was first thought of as limited to home handicrafts, but Sir Ian Fraser says that experience has shown that, given proper training, blinded men can operate machines in ordinary factories. St. Dunstan's has placed 120 men of the last war and 45 men of the recent war in munition and aircraft factories all over the country. Fifty St. Dunstaners of the recent war have been trained or are training as masseurs, and 47 as telephone operators, while others are following their older comrades as smallholders, poultry farmers, shopkeepers, and the like. One man has been placed as a labour manager, another as a research engineer, and a third has successfully passed his law examinations. St. Dunstan's has established homes in India and in South Africa, and it is expected that the former will prove to be a pioneer institution in the care of the blind in India. Altogether over 900 blinded Service men and women, victims of the second world war, have passed through St. Dunstan's.

A Missing Doctor

Surg. Lieut.-Cmdr. A. S. Playfair (Manor House, Bagdale, Whitby, Yorks) writes: I have been asked by the very anxious relatives of the Dutch Dr. J. W. Brinkman if I could help in any way to trace him. He was last heard of as a prisoner in Sandbostel Camp in Germany in April, 1945. Apparently he fell ill with typhus fever just before the liberation, and was afterwards under the care of British Service doctors. In June his name could not be found in the list of those who had died in the camp epidemic. Other arduous attempts to trace him have failed. I should be most grateful if you could publish this, with its request for any doctor who might have some information, however slight, to write to me as soon as possible.

Correction

Dr. D. G. McIntosh, referring to the letter on the erythrocyte sedimentation rate (Oct. 27, p. 584), says that owing to an oversight he omitted to add corrections to the list of references cited. The corrected references should read:

TROPICAL MEDICINE IN WAR AND PEACE

BY

C. M. WENYON, M.D., F.R.S.

In his presidential address to the Royal Society of Tropical Medicine and Hygiene on the subject of tropical medicine in war and peace Dr. Wenyon pointed out that the need for sending large numbers of men to tropical and subtropical countries during the war had been a great stimulus to research into methods of treatment and prevention of diseases prevalent in these areas. Much had been done under the general heading of hygiene and sanitation, which includes feeding, housing, and clothing, and one sometimes wondered whether the low incidence of some of the food- and water-borne diseases might not have been due to these measures rather than to some of the protective inoculations to which the troops had been subjected.

Position at End of Last War

In considering the war which has just ended he was led to wonder what lasting progress in tropical medicine had been made in the previous war. It seemed to him that much of the information acquired then was of a negative rather than a positive nature. Thus, it was realized that quinine was not such a good drug as we had supposed. As a prophylactic even in maximal doses it failed to prevent malaria entirely, though he was convinced that attacks of malaria were less frequent and less severe under its use. It was also found that quinine was more active against *Plasmodium falciparum* than against *P. vivax*, so that when mixed infections were treated it often happened that infection diagnosed as caused by the former subsequently relapsed as a *P. vivax* infection. This was due to the tendency of *P. falciparum* to keep *P. vivax* in abeyance. When *P. falciparum* was eliminated by quinine, *P. vivax*, less susceptible to the drug, asserted itself later on. During the last war it was also found that emetine was not such a good drug as we thought. Though active in acute amoebic dysentery and hepatitis, it too often failed to eradicate the dysentery amoebae in chronic cases. Emetine bismuth iodide was introduced and found to be a better means of administering emetine in many of these cases. In the early days of the last war it was thought that practically all cases of dysentery were of amoebic origin—a conclusion which resulted in wholesale injection of emetine. It was only later that it was discovered that the bulk of the cases were bacillary in nature. For this type of dysentery treatment was by salines and serum, but Dr. Wenyon thought that the latter did little if anything to control the disease. It was during the last war that it was first realized how widespread was amoebic infection amongst apparently healthy people—so much so that any idea which may at first have been entertained of isolating and curing all carriers had to be abandoned. The criterion for treatment or invaliding became a clinical one.

One of the main advances in tropical medicine in the last war was the demonstration by Leiper in Egypt that the two parasites *Schistosoma haematobium* and *S. mansoni* had exactly the same life history as that described by the Japanese for *S. japonicum*. Applying the technique which had been shown to him by Japanese helminthologists in Japan, Leiper quickly solved the bilharzia problem in Egypt, and thus showed that infection, there as in Japan, was acquired by wading or bathing in fresh water where infected snails were living. Another disease of importance in the last war was Weil's disease, our main knowledge of which again was due to earlier Japanese work. It was in the last war that Weil and Felix first isolated *Bacillus proteus* from the urine and blood of typhus patients and showed that the serum of such patients contained specific agglutinins against this organism. The reaction—the Weil-Felix reaction—had been extensively employed as a diagnostic procedure not only for louse-borne typhus but also for the typhus fevers of the Tropics. It was during this period that the louse was finally proved to be the vector of European typhus.

When the Second World War broke out it seemed that tropical medicine was very much in the same position as at the end of the last war, except in two important respects. First, the Germans had introduced atebrin (mepacrine hydrochloride) for the treatment of malaria; and, secondly, Americans had discovered a satisfactory method of vaccination against yellow fever. It seemed reasonable to conclude that the immunity of our troops to yellow fever in West Africa and elsewhere was largely due to the wide use of this system of vaccination. The serious outbreak of yellow fever in the Nuba Mountains in the Sudan in 1940 is an illustration of what can happen when the disease breaks out in a non-immune population.

Recent Advances in Malaria Treatment

With regard to advances in tropical medicine in the present war malaria occupied first place. The loss of the quinine-producing countries to the Japanese created a very serious situation, particularly as there was some reluctance to accept mepacrine as a satisfactory substitute. In spite of the fact that many reports indicated that it was effective alike for treatment and prophylaxis it was thought that the evidence that it could be taken for long periods without endangering the liver was inconclusive, particularly as in certain trials the drug appeared to be toxic. Fortunately for the progress of the war, Brigadier Fairley took the matter up very seriously in Australia, and at the experimental malaria centre which was established at Cairns he carried out exhaustive experiments on volunteers who were infected by means of mosquitoes imported by air from New Guinea. Mepacrine, quinine, and other drugs were administered under strict control, while regular blood examinations and analyses were carried out. Frequently the presence or absence of infections was determined by the inoculation of 250 c.cm. of blood into fresh volunteers. Often the men under prophylactic mepacrine were subjected to the most strenuous exercises and exposures with a view to imitating the severest active service conditions. The general outcome of this work, carried out with scientific thoroughness, was the clear demonstration that one pill of mepacrine (0.1 gramme) a day was sufficient to prevent men on active service in the most highly mosquito infested regions going down with malaria. It was also shown that one pill a day could be taken indefinitely with no more ill effect than a yellow coloration of the skin.

This dose of mepacrine was sufficient to eradicate entirely the malignant tertian parasite, but only kept in abeyance that of benign tertian malaria. In this respect mepacrine behaved like quinine. Attacks of benign tertian malaria occurred regularly after the cessation of prophylactic mepacrine when the malarial area had been left. Similar good results had followed the use of mepacrine in Burma and West Africa—a fact which appeared to indicate that the Pacific strains of the malaria parasites are no more susceptible to the drug than those of other localities. Brigadier Fairley's results convinced the most sceptical of military commanders, so that it was decided to enforce the one-pill-a-day regimen under strict military discipline—a decision which altered the whole course of the war in the South-West Pacific, Burma, and elsewhere.

Various attempts had been made to trace the immediate development of malaria sporozoites after they had been injected by mosquitoes. The most successful work was that of the American investigators Huff and Coulson working with the chicken parasite, *Plasmodium gallinaceum*. They had shown that, injected into the skin of fowls, the sporozoite did not enter the red blood corpuscle but penetrated mononuclear tissue cells, where in 42 hours it had become a schizont, which broke up into 100 to 200 merozoites. These merozoites entered other similar cells and the process was repeated. As these exoerythrocytic forms reproduced, some of the merozoites eventually entered red blood corpuscles and started the erythrocytic cycle. Now workers at Cairns had shown that after sporozoites had been injected into a volunteer his blood was infective to other volunteers for a few minutes, proving that sporozoites circulated in the blood for this short period only. The blood then became non-infective and remained so for seven to ten days, when it again became infective. This negative phase occurred whether prophylactic mepacrine was being taken or not; but if it was being taken the following positive phase which also supervened lasted only two or three days in the case of *P. falciparum* infections, but persisted in the case of *P. vivax* infections. This seemed to indicate that the sporozoite of human malaria parasites, like those of the chicken parasite, reproduced first of all in tissue cells and only later invaded the erythrocytes. It also showed that mepacrine had no action on these tissue forms. It was lethal only to the stages in the

THE RENAISSANCE AND ITS INFLUENCE ON ENGLISH MEDICINE, SURGERY, AND PUBLIC HEALTH*

BY

Sir ARTHUR SALUSBURY MacNALTY, K.C.B., M.D., F.R.C.P., F.R.C.S.

Fellow of University College, London

Thomas Vicary, Serjeant-Surgeon to King Henry VIII, King Edward VI, Queen Mary, and Queen Elizabeth, Master of the Barbers' Company, four times Master of the Barber-Surgeons' Company, and Surgeon to St. Bartholomew's Hospital, flourished as England's leading surgeon from 1527 to 1562. His life was passed in stirring times. A new world had been discovered by Columbus. Vicary saw the convulsive change produced by the Reformation and the dissolution of the monasteries, the fires at Smithfield and Oxford smoking with the blood of the martyrs, and above all he experienced the influence of the Renaissance and the birth of freedom of thought, individual initiative and action which guided him in his work for British surgery.

It was in the times of Thomas Vicary, then, that a new spirit arose in national thought; and amid a despotic rule, much oppression, and injustice it is possible to trace advances in medicine and surgery, in public health, in social medicine, and in culture and education.

How the "New Learning" came to England

It was not until the value of Greek thought became manifest to the practical Englishman that the influence of the Renaissance became widespread. This heritage was brought to England from Italy by a band of Oxford men known as the *Humanists*. The teaching of Colet, Grocyn, and Linacre, together with the young Thomas More, made Oxford famous as a seat of learning. Bishop Fox in 1516 founded Corpus Christi College at Oxford in the interests of the new learning, and John Fisher promoted the spread of Hellenic thought at Cambridge. Once the new learning was established in the universities it influenced national thought and practice.[1]

England in Tudor Times

The period of the Middle Ages, it has been remarked, had a childlike simplicity of outlook: it experienced extremes of joy and misery; everything was either black or white. It reverenced authority—that of the Church in religion, of the aristocracy in politics, of Aristotle, Galen, Pliny, and Pythagoras in science; it was inconsequent and thoughtless, and loved glitter and display. The England of Thomas Vicary's time was the nation's adolescence.[2]

Under Henry VII trade and manufactures, especially the woollen industry, were encouraged. The wealth in the country increased, but it was in the hands of a new and powerful class—that of the traders. Queen Anne Boleyn's grandfather was a London merchant, and the most powerful Ministers employed by a Tudor king were Wolsey, the son of an Ipswich grazier, and Cromwell, the son of a Putney blacksmith. The old villeinage or serfdom had gone. In the demand for wool the landlords found it more profitable to convert their waste and tilled land into pasture land for sheep. In the words of Thomas More,[3] "they thrust husbandmen out of their own and made sheep consume, destroy and devour whole fields, houses and cities." This caused much discontent and unemployment, and partly explains the popular support which Henry VIII received in the dissolution of the monasteries, which owned most of the land. The abolition of the craft guilds left guildsmen unemployed.

Thus the country in Tudor times was infested with destitute persons. Many became vagabonds, thieves, and murderers. The Poor Law legislation of Henry VIII and Edward VI put the onus of relief on the charity of local districts. It was not until the celebrated Poor Law Act of 1601, which made the maintenance of the aged and invalid poor and the provision of work for the able-bodied a statutory burden on the parishes through the levying of rates, that the problems of unemployment and destitution began to be handled effectively.

The extent of the population in Tudor times can only be broadly conjectured. A rough census was taken at the time of the Armada (1588), and was found to be something under five millions. The population, according to Froude,[4] had probably approached this figure many generations before. It had been a stationary population, and did no more than keep pace with the waste from disease, epidemics, high juvenile mortality, and civil and foreign war. Wages and the prices of food were regulated, so far as regulation was possible, by Act of Parliament. Wages were high and food was cheap.

On the whole, except for the destitute and the very poor, the standard of nutrition was high. More people probably died of overeating than under-nourishment; for the multitude of clerks, apprentices, retainers, and labourers shared the good things of the tables of their masters.[5] The Spanish nobles who came into England with King Philip were astonished at the diet which they found among the poor. "These English," said one of them, "have their houses made of sticks and dirt, but they fare commonly so well as the King." "What comyn folke in all this world," says a State paper in 1515,[6] "may compare with the comyns of England in riches, freedom, liberty, welfare and all prosperity? What comyn folke is so mighty, so strong in the felde, as the comyns of England?"

The success as rulers of Henry VIII and Elizabeth lay in the fact that their strength rested in the support of the common people and the middle classes. To this end wages and food prices were controlled, pageants were provided for their amusement, and contentment prevailed. The Renaissance introduced a new style of architecture and there was much building of houses or extensions to existing mansions. These dwellings were surrounded by parks and pleasant flower and herb gardens. The princes built palaces, such as Richmond, Nonsuch, Greenwich, and Hatfield. Cardinal Wolsey's edifices at Hampton Court and Whitehall were both seized and completed by Henry VIII. The nobles, squires, and wealthy merchants followed the royal example, and new colleges were founded and built at Oxford and Cambridge. Dress, as we know from the portraits of Holbein, was ostentatious and costly among the courtiers and the well-to-do.

In various ways the amusement of all classes of society was catered for; there were masques, theatrical performances, archery, athletic sports, fairs, pageants, and shows, bull- and bear-baiting, badger-drawing, and cock-fighting: while public erythrocytes. As mepacrine entirely eradicated a *P. falciparum* infection it would seem that the tissue phase of this parasite was of short duration—perhaps two or three cycles only. The difficulty about these tissue forms of human malaria parasites was that they were at present purely hypothetical, as no one had yet observed them. Intensive researches were going on at the present time to discover such forms if they existed.

---

* The Thomas Vicary Lecture, delivered at the Royal College of Surgeons on Nov. 1, 1945.

From the point of view of malaria prophylaxis the discovery of D.D.T. was of the utmost importance. Used in sprays in enclosed places it would destroy all mosquitoes that entered, and employed on water it would kill all mosquito larvae. Simmons, working in the U.S.A., had recently shown that the use of 20 mg. of D.D.T. per square foot of surface in a room would lead to the death of 60 to 90% of all wild mosquitoes which entered 20 weeks later. On water 1/10 lb. per acre would destroy all mosquito larvae. The discovery of dimethyl phthalate as an effective repellant was also of importance in malaria prophylaxis. It seemed that for the first time repellants had been discovered which actually did what was claimed for them.

Typhus and the Dysenteries

Another disease, Dr. Wenyon said, which threatened our troops in the South-West Pacific islands and Burma was scrub typhus. Here again, under the name tsutsugamushi disease, this rickettsial infection had been thoroughly investigated by the Japanese. The vector, being a mite, was very difficult to avoid, but it was found that dibutyl phthalate applied to the skin and to clothes and bedding not only repelled the mites but actually killed those coming into contact with it. A formalinized vaccine prepared from the lungs of nasally infected cotton-rats was in process of trial in Burma when hostilities ceased. Louse-borne typhus was a menace in North Africa, Iraq, Persia, and other places. A formalinized rickettsial vaccine prepared from egg-yolk cultures by the process of Cox and Craigie was employed, and it is reported to have given some protection. There was no doubt, however, that the use of D.D.T. as a dusting-powder and in solution for the impregnation of clothing had been the main reason for the low incidence of typhus fever and other louse-borne diseases. It had been shown that a soldier's shirt, once impregnated, would retain its insecticidal properties through many launderings —practically during the whole life of the shirt. Much attention during the war had been given to the possibilities of improving methods of diagnosis by agglutination and complement-fixation tests employing rickettsia as antigen, but for routine diagnosis the old Weil-Felix reaction had still to be relied upon.

Under the heading of dysenteries the most remarkable result was the demonstration by Marshall and his co-workers in the U.S.A. that sulphaguanidine was almost a specific remedy. His results were quickly confirmed in Egypt, and as soon as adequate supplies were forthcoming its use became general. It appeared that with the introduction of this drug bacillary dysentery ceased to be one of the major war problems. It seemed that sulphasuxidine, less readily absorbed from the intestine than sulphaguanidine, might be an even better drug for this purpose. At the outbreak of this war the method of treating amoebic dysentery was very much in the same position as it was in the last war. Emetine was being administered by subcutaneous injection or orally as emetine bismuth iodide, while this was supplemented by enemata of yatren or diodoquin by the mouth. In spite of this treatment many cases proved resistant, particularly those with a long-standing colitis. In cases of this kind Lieut.-Col. Henderson noted that improvement often followed the use of penicillin or one of the sulphonamides. This was due apparently to the eradication of secondary bacterial infections. He also noted that after this initial improvement the amoebic infection might be found to be susceptible to the routine anti-amoebic course of treatment. This observation disproved at once the view that cases resisted treatment because the amoebae had become emetine-fast. Actually there was no satisfactory evidence that emetine-fast strains of amoebae existed.

The Transmission of Kala-azar

During the war, but not perhaps as the result of a particular war effort, an important investigation which had occupied the attention of workers in India for many years was brought to a successful completion. This was the study of the method of transmission of kala-azar. The sandfly *Phlebotomus argentipes* was first suspected on epidemiological grounds. It was then shown that the leishmania developed into flagellates in the stomach of the sandfly and invaded the proboscis. Hamsters were infected by the bites of sandflies, and, finally, infected sandflies were allowed to feed on five volunteers in a district where kala-azar did not occur. All five became infected. The whole of this investigation, occupying over 20 years, was an excellent illustration of team-work in which many people played a part. In the field of leishmaniasis another interesting development was the demonstration by Russian observers in Middle Asia that in certain localities where oriental sore was very common gerbils and sousliks acted as reservoirs for the human virus. In the burrows occupied by these rodents in the desert sandflies lived and multiplied. The sandflies became infected from the rodents and handed on the infection to other rodents. In the burrows the climatic conditions were constant throughout the year, so that there was no seasonal incidence of the infection. At certain seasons, however, sandflies left the burrows and passed on the infection to human beings.

During the war outbreaks of schistosomiasis had occurred and attempts had been made to find better remedies than tartar emetic or fouadin, but, so far as Dr. Wenyon was aware, without result. Cases of filariasis had occurred in the South-West Pacific area, but there was still no remedy for this condition. The discovery of filariasis in the cotton-rat had led to this animal, as well as the dog, being used for experimental purposes. It might be that these animals would contribute to the discovery of a treatment, which was long overdue.

Future Teaching Facilities

These, said Dr. Wenyon in conclusion, are some of the more important advances in knowledge of tropical medicine which have been made during the war, and they show what can be done when there is a sufficient incentive. Now that the war is over one wonders whether research in tropical medicine will be carried on with the same enthusiasm and determination. In the U.S.A. interest in tropical medicine has increased steadily, so that there is hardly a tropical disease which is not under investigation in some form or another at the present time. There is no doubt that the U.S.A. will continue to add much to our knowledge of this subject during the years that are before us.

In this country the war has given rise to many difficulties, so that we are now in a much worse position than we were as regards facilities for teaching tropical medicine and caring for those returning to this country suffering from tropical diseases. Sir Patrick Manson, from painful personal experience in China, realized how essential it was to have in London a centre where tropical medicine could be taught to those who were going to practise in the Tropics. With the help of Joseph Chamberlain and the Seamen's Hospital Society, he founded in 1899 at the Royal Albert Dock the School of Tropical Medicine and the Hospital for Tropical Diseases. This centre functioned very successfully for a number of years till shortly after the last war a move was made to the building at Endsleigh Gardens. This offered few if any advantages over the old school at the Albert Dock, except that it was more accessible for students and teachers. Later still the London School of Hygiene and Tropical Medicine was founded as the result of a gift from the Rockefeller Foundation, and for the first time the School of Tropical Medicine which was incorporated was separated from the Hospital for Tropical Diseases. Before this there was established at Hamburg the Institut für Schiffs- und Tropenkrankheiten, on the pattern of the original centre at the Royal Albert Dock. It possessed a hospital for tropical diseases with an out-patient department, teaching laboratories, lecture theatres, and research laboratories. There is no doubt that it was planned on a more ambitious scale than the London School, but it was well organized, possessed a competent staff, and was very successful in every way.

It seemed to many who visited the Hamburg institute inexplicable that it was not found possible for London—the centre of the British Empire, with all its colonial possessions and dependencies in tropical lands—to have a Tropical Medical Centre at least as good as, if not better than, the one in Hamburg, which has now been razed to the ground. During the war our facilities for dealing with tropical diseases and teaching executions, whipping at the cart's tail, ducking a scold, and burning of witches and heretics provided more sadistic excitement. Such was "Merrie England" in the time of Thomas Vicary.

Education

The Tudor monarchs encouraged and practised scholarship. Linacre was Prince Arthur's tutor. The Oxford humanists, as we have seen, had established the new learning in the universities. Linacre founded medical lectures which bear his name at Oxford and Cambridge. Yet if it had not been for Sir Thomas Smith, "the flower in his time of the university of Cambridge," the universities might have perished at the Reformation.

Thomas Vicary knew Latin, but was probably not a classical scholar. However, he emphasized the value of a good general education for the surgeon. He was to be reasonably well versed in philosophy, grammar, and rhetoric, and a "lettered" man. Vicary's knowledge of and his affection for the works of Guido de Cauliaco are indicated by the request in his will "unto the hawle of my company one book called Guido." This was probably Guido's *Cyrurgia* of 1363. At the grammar schools the boys were taught to read, write, and speak Latin. At a few schools, like St. Paul's, Greek was taught and a little mathematics. The pupils were expected to know how to read and write before entrance—a fact which implies the existence of elementary schools, kept chiefly by the clergy. Tyndale's translation of the Bible into English undoubtedly stimulated the spread of elementary education. On the whole there was less illiteracy among the people of England in the sixteenth century than in the first half of the nineteenth. It may be assumed that the medical student of Tudor times received a reasonable general education, particularly if he went to the university before entering on his professional studies.

Social Medicine and Public Health

In reviewing the general state of England in Tudor times we have noted signs of progressive prosperity in trade and commerce, the abolition of serfdom, and in the main a well-nourished and athletic population. When we turn to the consideration of social medicine and public health the picture is much less favourable, but there are signs of gradual improvement.

It is in Henry VIII's reign that the beginnings of an enlightened public health policy in regard to water supplies can be noted, for in 1532 there was passed the important Act of Parliament (23 Henry VIII, C. 5) which appointed Commissioners of Sewers in all parts of the kingdom. Though much of the work of the Commissioners was riparian in character and directed towards preventing encroachments of the sea, flooding of low grounds, and maintenance of river banks, regulations were also made against trade effluents, deposits of rubbish in rivers, and pollution of rivers, streams, and wells. The larger towns were provided with a regular water-system with public standpipes, and water sometimes was laid on to the houses. London for a long time had been well supplied with water, but under the Tudors seven or eight more conduits were set up from which fresh water was hawked about the streets in barrels. These improvements in water supplies probably owed much to Sir Thomas More, who was appointed one of the Commissioners of Sewers along Thames bank between East Greenwich and Lambeth in 1514.[7]

Epidemic Diseases

There was much disease in England in Thomas Vicary's days. "Surfeits," scurvy, scabies, gout, and stone prevailed, and syphilis was a deadly scourge, as Dr. Johnston Abraham[8] has shown. Measles, smallpox, tuberculosis, typhus, and dysentery took a heavy toll, but the deadliest epidemics were bubonic plague and the "sweating sickness."

Plague

Plague had remained endemic in England since 1349, the terrible year of the Black Death, which destroyed two million people—half the existing population. At the beginning of the sixteenth century there was a general recrudescence of the disease. From 1511 to 1521 there is not a single year without some reference to the prevalence of plague in the letters of Erasmus and elsewhere.

The chief protective measure was flight from the infected locality, the King and the Court setting the example. Sir Thomas More, in a charge he made to the Mayor of Oxford in 1518, ordered inhabitants infected with the plague to keep in their houses and to "put out wisps and bear white rods." They were forbidden to have animals in their houses, and officers were required to keep the streets of the town cleansed and burn refuse. This procedure was later enforced by the London plague bills of mortality in 1532, parish registers of deaths (1539), and the plague orders of 1543, which were adopted in the Elizabethan regulations. The white wand became the insignia of the "searchers" of infected houses (which had to be marked and closed) and the bearers of the dead. Additional orders later made by the Corporation of London prescribed burning of infected clothing and bedding, cleansing of streets, closing infected houses for forty days, and many regulations about scavenging and sanitation.

The Sweating Sickness

The sweating sickness was one of those mysterious maladies, like influenza and *encephalitis lethargica* in our own time, which suddenly make their appearance, wreak havoc and destruction for a while, and then as suddenly disappear.[9] Five epidemic outbreaks of sweating sickness occurred in England in the sixteenth century. The disease was first noted in August, 1485. In 1502 it prevailed in the West Country, and Prince Arthur probably succumbed to it at Ludlow. In 1507 a milder outbreak occurred, but 1517 saw a third and much more severe epidemic, half the population in a town perishing in some instances. The fourth epidemic, in 1528, was one of great severity. In London that summer the mortality was very great. "One has a little pain," wrote Du Bellay,[10] the French Ambassador, "in the head and heart. Suddenly a sweat breaks out, and a physician is useless, for whether you wrap yourself up much or little in four hours, sometimes in two or three, you are despatched without languishing."

The fifth and final epidemic was in 1551, and was well described by Dr. John Caius in a treatise entitled *A Boke or Conseil against the Disease Commonly Called the Sweate or Sweating Sickness* (1552).* It did not cause much fatality among the poor, but chiefly affected the rich and those who were free livers. Caius noted that "they who had this sweat were either men of wealth, ease, or welfare, or of the poorer sort such as were idle persons, good ale drinkers, and tavern haunters." Dr. Creighton,[11] the epidemiologist, and Dr. Michael Foster[12] considered that the only disease of modern times which bears any resemblance to sweating sickness is *miliary* fever (*schweiss-friesel, suette miliare,* or "the Picardy sweat"), a malady repeatedly observed in France, Italy, and South Germany, but not in the United Kingdom. It was characterized by intense sweating and an eruption of vesicles, lasted longer than sweating sickness, occurred in limited epidemics, and was usually not fatal. The first epidemic was seen in 1718, and it continued to 1906, and even later. There were 175 epidemics in France alone.

Three Tudor Pioneers in Public Health

Sir Thomas More (1478–1535) is well known as Speaker of the House of Commons, Lord Chancellor, eminent humanist, saint, and martyr. In addition he was a great health reformer. We have to wait until the nineteenth century for a man of equal vision and breadth of view to appear in Edwin Chadwick.

More's friendship with Linacre probably first turned his attention to the problems of public health. His work as Commissioner of Sewers and in controlling plague has already been described. In his *Utopia,* printed at Louvain in 1516, he gave an account of "No-where"—the imaginary Commonwealth of the Renaissance idealists. The citizens of Utopia esteemed health as "the greatest of all pleasures." Inspired by his know-

---

*I am indebted to Prof. W. G. Hoskins for a reference in Nichol's *History of Leicestershire* (p. 891), wherein is given an extract from the Loughborough parish register for 1551, as follows:—1551, June: "The Swat, called the New Acquaintance, alias Stoupe Knave and Know Thy Master, began 24th of this month." The register then mentions 12 persons who were buried in 12 days, and then goes forward to another page, where it is written at the top, "The Sweat or New Acquaintance," and mentions seven names all buried in three days, in all 19 in six [sic] days. After this it seems to cease.

tropical medicine have not improved. The Hospital for Tropical Diseases had to be evacuated for reasons of safety. The building was subsequently badly damaged and as a hospital was finally abandoned. It has been taken over by the Government, has been repaired, and is now occupied by a department of the Ministry of Pensions. The London School of Hygiene and Tropical Medicine has also been damaged, so that there is hardly enough space available for the primary work of the School, which is not tropical medicine but hygiene with special reference to this country. For purposes of teaching and research in hygiene more space is required, so there is a danger that tropical medicine will be cramped for room, if not crowded out.

A Great Opportunity

It does seem that there is at this moment a great opportunity for establishing in London a Tropical Medical Centre with a hospital, say, of 300 beds, for the care of sick people from the Tropics, laboratories and lecture theatres for the teaching of tropical medicine in close association with clinical teaching in the hospital, research laboratories in tropical medicine and allied subjects, and a well-advertised out-patients department where the many casual people from the Tropics who find themselves ill in London could receive advice and treatment. To carry out such a plan satisfactorily it would be necessary to build, which is a difficulty at the present time, though provision for the care of the ever-increasing numbers of persons returning to this country suffering from tropical diseases and requiring special treatment might be a sufficient excuse for breaking the rule. It seems that if building is not possible at the moment a suitable site might at least be secured before it is too late to obtain one and the site marked as the future Hospital for Tropical Diseases and School of Tropical Medicine. A great deal has been heard of colonial development and plans for the improvement in health and standard of living of the natives and others who reside in our tropical possessions. Large sums of money are spoken of as earmarked for these improvements. It seems that no single object would do more to bring about these results than the establishment—or rather re-establishment—in London of a Tropical Medical Centre. It would restore the position formerly held by this country in the field of tropical medicine, would be a monument to the many pioneers who devoted themselves to the study of tropical diseases, and would be a centre of tropical medical activity worthy of the British Empire.

MEDICAL WAR RELIEF FUND

AN APPEAL

Five years have passed since an appeal to the profession for subscriptions to the Medical War Relief Fund was published by the newly established Committee of the Fund, composed of the Presidents of the three Royal Colleges in England, the President of the Royal Medical Benevolent Fund, and the Honorary Officers and Chairman of the Charities Committee of the British Medical Association. The response was immediate and gratifying, and many subscribers have not waited to be asked again but have sent frequent contributions throughout the five years of the Fund's existence. The generosity of the profession has enabled the Fund to do grand work in helping British doctors to whom the war has brought acute financial difficulty and the widows and children of those who have lost their lives on the battlefields, on the high seas, and in the "blitz."

The time has come to appeal again. The Fund is now receiving more frequent applications for a larger measure of help than ever before, and probably the peak is still to come. Many medical officers released from the Services need very substantial assistance in re-establishing themselves in civil life. To help them effectively it is necessary to help them generously. The balance remaining in the Fund is only some £25,000, and it is expected that at least £100,000 will be required during the next year.

The Committee of the Fund is deeply grateful for the support received in the past. It appeals with confidence for continued and increased support now. To provide the relief sorely needed by those who have risked much and suffered much and by the dependants of those who will not return is a debt of honour which the profession must not and will not fail to discharge. But a lot of money will be needed to "finish the job." Every member of the profession is asked to contribute as generously as his or her means permit, and the committee appeals particularly to the generosity of those who have escaped the major financial hardships suffered by so many of their colleagues in the "blitzed" and evacuated towns and districts.

The fifth annual report of the Fund is published in the *Supplement* this week. The Honorary Secretary will gladly provide any further information desired. Cheques should be made payable to the Medical War Relief Fund and sent to the Honorary Treasurer of the Fund at B.M.A. House, Tavistock Square, W.C.1. A list of donations already received or promised in response to the new appeal is printed below.

H. GUY DAIN, *Chairman.*
JOHN W. BONE, *Honorary Treasurer.*

Donations Received or Promised

£210.—Royal College of Physicians, London (2nd donation).

£105.—Col. L. W. Harrison, London (2nd donation); Dr. Wm. Paterson, Harlesden (3rd donation); Sir Alfred Webb-Johnson, London (2nd donation).

£100.—Mr. Noel F. Adeney, Bournemouth (2nd donation); Dr. Emily Mecredy, London; Northants Medical Charity (13th donation); Dr. C. J. Penny, Winchester (2nd donation).

£52 10s.—Prof. A. H. Burgess, Cheadle (3rd donation); Mr. W. Sampson Handley, London (2nd donation); Dr. P. H. Midgley, Hale, Ches. (2nd donation).

£50.—Anonymous; Mr. John Bastow, Bath (2nd donation); Dr. B. E. A. Batt, Bury St. Edmunds (2nd donation); Dr. J. C. Matthews, Downton (2nd donation); Prof. G. Grey Turner, Taplow (3rd donation).

£30.—Mr. A. Tudor Edwards, London (2nd donation); Dr. Peter Macdonald, York (2nd donation).

£26 5s.—Dr. J. A. Brown, Birmingham (3rd donation); Sir Harold D. Gillies, London; Dr. W. F. T. Haultain, Edinburgh (5th donation); Mr. Eardley Holland, London (2nd donation); Dr. C. P. Lapage, Manchester (4th donation).

£25.—Dr. J. W. Bone, Luton (3rd donation); Dr. H. Guy Dain, Birmingham (2nd donation); Prof. G. B. Fleming, Glasgow (2nd donation); Dr. L. G. Glover, London (2nd donation); Dr. Charles Hill, London (2nd donation); Dr. J. A. McClintock, Church Stretton (7th donation); Lord Moran, London (2nd donation); Mr. H. Campbell Orr and Mrs. Orr, Wolverhampton (2nd donation); Mr. H. S. Souttar, London (2nd donation); Dr. C. M. Stevenson, Cambridge (3rd donation); Miss Margaret C. Tod, Manchester; Dr. T. H. Whittington, London (2nd donation).

£21.—Anonymous; Dr. R. T. Brain, London (2nd donation); Dr. J. B. Jessiman, Malvern Link (2nd donation); Dr. Mary Esslemont, Aberdeen (2nd donation); Sir Hugh Lett, Richmond (3rd donation); Dr. Colin D. Lindsay, Plymouth (3rd donation); Mr. R. J. McNeill Love, London; Miss Gladys M. Sandes, London.

£20.—Dr. Thomas Fraser, Aberdeen (2nd donation); Mr. E. Lewis-Lilley, Leicester (3rd donation); Dr. and Mrs. J. Vaughan Jones, Leeds (3rd donation); Mr. Donald Watson, Bradford (3rd donation).

£15.—Dr. R. W. Cockshut, London; Dr. W. Cliff Hodges, Godalming.

£10 10s.—Prof. Seymour Barling, Birmingham (2nd donation); Miss Margaret Basden, London (2nd donation); Dr. Geoffrey Bourne, London; Dr. D. W. A. Bull, Stony Stratford (3rd donation); Sir Farquhar Buzzard, Oxford (2nd donation); Mr. V. Zachary Cope, London (4th donation); Dr. R. W. Craig, Edinburgh (2nd donation); Sir Allen Daley, London (2nd donation); Mr. H. N. Fletcher, Hove (3rd donation); Dr. A. E. Gow, London; Dr. Frank Gray, London; Dr. E. A. Gregg, London (2nd donation); Dr. A. H. Habgood, Stony Stratford (2nd donation); Dr. L. Leigh Hadley, Birmingham (2nd donation); Mr. S. L. Higgs, London; Sir Robert Hutchison, Streatley (2nd donation); Dr. Agnes V. Kelynack, Harpenden; Mr. C. E. Kindersley, Bath (2nd donation); Dr. J. F. Lambie, Glasgow (3rd donation); Mr. S. Gray MacDonald, London (2nd donation); Sir Ewen Maclean, Cardiff (2nd donation); Mr. W. H. McMulien, London (3rd donation); Dr. and Mrs. A. Macrae, London (4th donation); Mr. R. L. Newell, Manchester; Mr. L. E. C. Norbury, London (2nd donation); Dr. W. H. Pollard, Birmingham (3rd donation); Dr. H. W. Pooler, Ashover (2nd donation); Dr. A. M. Richards, Oxford (2nd donation); Dr. A. C. Roxburgh, London (2nd donation); Dr. S. Cochrane Shanks, London; Dr. S. Watson Smith, Bournemouth (3rd donation); Dr. W. D. Steel, Worcester; Mr. W. E. Tanner, London (2nd donation).

£10.—Mr. Victor Bonney, London (2nd donation); Dr. F. Chown, Penzance (2nd donation); Mr. C. B. Goulden, London; Dr. G. Graham, London (2nd donation); Dr. Arnold McMillan, New Romney (2nd donation); Mr. A. M. A. Moore, London (2nd donation); Dr. J. C. Muir, Box (2nd donation); Dr. Donald Paterson, London (2nd donation); Mr. G. A. Bagot Walters, Lincoln (5th donation); Dr. N. E. Waterfield, Little Bookham (2nd donation).

£6 6s.—Dr. C. G. Martin, London (2nd donation).

£5 5s.—Prof. F. J. Browne, London; Mr. Stanford Cade, London; Mr. L. Dougal Callander, Doncaster (3rd donation); Mr. J. Inglis Cameron, Glasgow (3rd donation); Dr. O. C. Carter, Bournemouth (3rd donation); Sir Maurice Cassidy, London (2nd donation); Dr. H. A. Clegg, London (2nd donation); Dr. G. H. Davy, London; Dr. D. V. Hubble, Derby (3rd donation); Prof. C. F. W. Illingworth, Glasgow (2nd donation); Mr. F. A. Juler, London (3rd

ledge of the principles of Greek medicine, More[3] applied his learning to a description of desirable public health provision in Utopia. He envisaged a well-built city with gardens and open spaces, a public water supply, drainage, and cleansed streets, with public abattoirs outside. Public hospitals were provided for the treatment of rich and poor, and isolation hospitals for cases of infectious disease. Other amenities included communal meals; the safeguarding of maternity with municipal nurses for infant welfare; nursery schools (or crèches) for children under 5; free universal education for all children, with continuation, adolescent, and adult schools; religious instruction, industrial welfare, enlightened marriage laws, and eugenic mating and obedience to the laws of health, including fresh air and sunlight and active occupation without undue fatigue.

It is a comprehensive programme of social medicine which, written in the sixteenth century, expresses many of the aspirations of to-day. If Sir Thomas More had had a wise and discerning master, if that master had given him due authority and powers in administration, England would not have had to wait three hundred years for the initiation of national public health. Instead Henry VIII sent Sir Thomas More to the scaffold.

Sir Thomas Elyot (? 1490–1546), diplomatist and author, was also an enlightened social reformer. He was traditionally an M.D. of Oxford, although no evidence of this is extant.[13] He was English Ambassador to the Court of the Emperor Charles V, served on several foreign missions, and was knighted by Henry VIII, being the first medical man (according to Dr. S. D. Clippingdale) to be thus honoured. He wrote *The Castel of Health* (London, 1534), a Latin–English Dictionary (1538), and *The Boke named the Governor* (1531), a treatise on the education of statesmen. *The Castel of Health* is a medical treatise of prescriptions for various ailments, and Elyot gives an account of the disorders from which he himself suffered.

The third Tudor pioneer in public health was Dr. Andrew Boorde or Borde (? 1490–1549), traveller-physician—"Andreas Perforatus," as he humorously styles himself. It was at Montpellier that he wrote his *Fyrst Boke of the Introduction of Knowledge*, published ? 1547; the first printed *Handbook of Europe*; his *Dyetary*, published in ? 1542; his *Breuyary of Health*, published in 1547; and his lost *Boke of Berdes* (beards), condemning them. Boorde's *Dyetary* is an excellent manual of hygiene based on his medical experience and full of sound common sense. On nutrition he gives good advice:

> "Two meales a daye is suffycyent for a resting man; and a labourer may eate three tymes a daye; and he that doth eate ofter, lyveth a beestly lyfe. . . . Also sondry meates eaten at one meale is not laudable; nor it is not good to syt long at dyner and supper. An houre is suffycyent to syt at dinner; and not so longe at supper."

He also points out the unwise custom of beginning with heavy meats and only putting on better, light, and nutritive meats when the appetite is assuaged. The prodigious feasts of the time show that little heed was paid to his counsels. The instructions in the book for choosing a site and for the building and hygiene of a country house could hardly be bettered by the textbooks of to-day.

These three men—More, Elyot, and Boorde—were far ahead of their age. Under the rising sun of the Renaissance they grasped the fundamental principles of social medicine, nutrition, and education, and set forth their application in their writings. Much of the seed lay dormant for centuries. It is only in the public health and social reform of to-day that we begin to reap the harvest of their work.

The Hospitals

One of the most evil results of the dissolution of the monasteries was the abolition of the hospitals maintained by the monks for the care and treatment of the sick poor. Sir Thomas More in his *Supplication of Souls* exposed this short-sighted policy, but Henry VIII ignored the advice.[14] By 1539 the total number of suppressed religious establishments was 655 monasteries, 90 colleges, 2,374 chantries and free chapels, and 110 hospitals.

The Corporation of London foresaw the evil that would result, and in 1538 Sir Richard Gresham, the Lord Mayor, asked that the three remaining hospitals, St. Mary Spital, St. Bartholomew's, and St. Thomas's, and, also, the Abbey of Tower Hill, might be placed with their revenues at the disposal of the Mayor and aldermen, so that "all impotent persons not able to labour might be relieved."[15] Nothing was done until 1544, when Henry re-founded St. Bartholomew's Hospital, though he afterwards resumed possession of it. Henry's physicians said the only way of getting the King to listen to reason was to have him fall ill. This was exemplified on his death-bed in 1547, when he made the comprehensive agreement with the citizens which led to his posthumous, if unmerited, distinction as first founder of the five "Royal Hospitals"—St. Bartholomew's, St. Thomas's, Christ's Hospital, Bethlem Hospital, and Bridewell. It was through the efforts of the City Corporation that these hospitals were preserved.

Revival of Medicine

The first beginning of organization of the medical profession in England was undoubtedly due to the influence of Henry's physician, Thomas Linacre, a medical graduate of Padua and Oxford, who had seen the reputation and distinction to which the medical profession could attain in Italy under the star of the Renaissance, and in the interests of the public wished to separate physicians and surgeons from the horde of empirics and quacks. As is well known, he followed up the Act regulating the practice of medicine in London by founding the Royal College of Physicians of London in 1518. The letters patent state that to the establishment of this incorporation the King was moved by the example of similar institutions in Italy and elsewhere, by the solicitations of at least one of his own physicians, Thomas Linacre, and by the advice and recommendation of his chancellor, Cardinal Wolsey. The letters patent were confirmed by Statute 14, Henry VIII. The original founders of the College, John Chambre, Thomas Linacre, Ferdinandus de Victoria—all physicians to the King—Nicholas Halsewell, John Francis, and Robert Yaxley, with the addition of two other physicians, Richard Bartlot and Thomas Bentley, were named Elects, who should yearly appoint from among themselves a President. No person, except a graduate of Oxford and Cambridge, without dispensation, was to be permitted to practise physic throughout England unless he had been examined and approved by the President and three of the Elects.

> "It was expedient and necessary to provide that no person be suffered to exercise and practise physic, but only those persons that be profound, sad and discreet, groundedly learned and deeply studied in physic."

The apothecaries were then members of the Grocers' Company, by whom they were regulated. All apothecaries had their wares and medicaments examined by four representatives of the College of Physicians.

As indicative of the influence of the Renaissance in medicine it is to be noted that three at least of the founders possessed foreign medical degrees. John Chambre, a priest, was M.D. of Padua and Warden of Merton College, Oxford; Thomas Linacre, who took orders late in life, was M.D. of Padua; and Ferdinand de Victoria, who was also physician to Queen Katherine of Aragon, had probably a Spanish medical degree. Six of the eight Elects, if not all, were Doctors of Medicine of Oxford, so that this university had the major share in founding the College. Oxford in Tudor times had a prescribed medical course. The M.D. could not be got in less than fourteen years. The Statutes demanded the initial Arts course to the M.A. degree, then a faculty course of seven years.

Several papers have been written by Dr. Goldwin Smith[16] and others with the object of emphasizing the low standard of medical practice in these times. Dr. Edgar[17] and Dr. Pomeranz[18] have pointed out with apt quotations what a poor figure the physician cuts in the plays of Shakespeare and in those of other Tudor dramatists. But the doctor has always been the theme of satire on the stage, from the comedies of Plautus and Terence to *The Doctor's Dilemma*. It has also been remarked that the physicians of the Tudor Age made few contributions to the advancement of medical knowledge. Such a stricture is too severe, when the writings of John Caius on the Sweating Sickness and those of Sir John Elyot and Andrew Boorde are remembered. Queen Elizabeth termed Caius "the most learned physician of his age"—an epithet which posterity has confirmed. Caius was a physician, an anatomist, a great

TUBERCULOSIS IN CHILDHOOD

"The Papworth experiment proves conclusively that it is unnecessary for childhood tuberculosis to occur even where the danger of massive infection is potentially present. It shows that this can be achieved without breaking up the family and, so far as the children have been followed, the results have a more lasting value than even the most optimistic of Papworth's supporters had dared to hope." This statement was made by Dr. ALAN MONCRIEFF in the course of delivering the third Varrier-Jones Memorial Lecture at the Hospital for Sick Children, Great Ormond Street, on Nov. 14. The chair was taken by Sir Wilson Jameson, Chief Medical Officer to the Ministry of Health.

The lecturer expressed grave concern as to the adequacy of existing methods of diagnosing, and combating, tuberculosis in childhood. Not only was it more difficult to detect the early signs of tuberculosis in children than in adults; the measures to be taken after diagnosis presented many problems. Notification, indeed, often made it difficult for suitable treatment to be arranged, because it was by no means always desirable for a child to be sent to a sanatorium; yet failure to notify prevented the other and valuable parts of the antituberculosis machine from coming into action. The results disclosed by Dr. Brieger's survey, *The Papworth Families,* proved beyond question Papworth's remarkable success in protecting children against the disease, and Dr. Moncrieff added that "much more could be done by local authorities to imitate the conditions achieved at Papworth."

A substantial proportion of the deaths from tuberculosis could be ascribed to infected milk. Compulsory pasteurization of all milk would "completely eliminate this menace," but meantime "bovine tuberculosis must still be faced as a serious cause of easily preventable mortality in childhood."

Special children's diagnostic clinics as suggested by the British Paediatric Association should be set up for the full examination of children who had been in contact with cases of adult pulmonary tuberculosis. He cited a case in which a sick child, admitted to hospital with no obvious signs of tuberculosis, was found to be suffering from the disease. When the parents were examined it was discovered that the father, who had never been ill, was a sufferer too. But for the accurate diagnosis in the case of the child she might well have remained, all unknowing, in contact with the tuberculous father, "and in such a case a fatal ending was more than likely."

Where home conditions could not be altered so as to protect children against infection, Dr. Moncrieff recommended the French Grancher system, under which children threatened by contact infection were boarded out in healthy families. He welcomed the news that a children's hospital was to be built at Papworth. In conclusion he advised: (1) increased recognition of the dangers of "droplet" infection from adults; (2) improved machinery for accurate diagnosis; (3) an effort to realize Papworth conditions in all tuberculous households; and (4) improved institutional facilities for child sufferers from the disease and a greater use of boarding-out facilities for healthy contacts. The fulfilment of such a programme would "go a long way to stamping out an essentially preventable disease."

COVENTRY SEES IT THROUGH

Besides the concentrated bombing attacks which it endured in 1940 and 1941, Coventry had a full share of the grimness of the home front during the war years. Among other factors menacing the city's health were the shelter life of a large number of its inhabitants, the strain of concentrated effort in the munition factories, large-scale immigration of industrial workers, and domestic overcrowding. Nevertheless the health report for 1944, which discloses certain local facts and figures relating to the five previous years, shows that the health of the city has been maintained at a satisfactory level. Since local raids stopped in the summer of 1941 the population has grown progressively, and in 1944 it stood at close upon a quarter of a million, which is several tens of thousands above the pre-war level. The death rate in 1944 was 9.7, as against 10.3 for the previous year and 11.6 for England and Wales as a whole, while the infant mortality, 48.4 to 1,000 births, was the lowest since 1937 and compares with 52 for the large towns and 46 for England and Wales. The comparative freedom from epidemic influenza during the war years is a matter of comment. It is estimated that 87% of the school-children and 49% of the pre-school children are immunized against diphtheria. One of the few shadows on the wartime health picture of Coventry is the increase in tuberculosis. During the last year 356 cases of pulmonary tuberculosis were notified, as compared with 231 in the last pre-war year. This higher incidence is attributed to the strain of war work and the limitations placed upon ventilation of homes and work-places by the black-out; the wartime dietary also cannot be exonerated. Venereal diseases make another blot on the record. The total number of new cases appearing at the treatment centres in 1944 was 1,322, a higher number than in any war year and comparing with 571 in 1938. The bombing has left a legacy of domestic overcrowding, damaged houses in occupation, and rat infestation of bombed sites which has taxed the sanitary resources of the city to the full.

CLINICAL PATHOLOGY IN CZECHOSLOVAKIA

A recent development in the organization of the medical services of the Czechoslovak Republic is the formation of the Czechoslovak Association of Clinical Pathologists. This step was closely linked with those steps taken by the Ministry of Health for the establishment of a penicillin service. Shortly after the liberation of Czechoslovakia the Ministry called upon Docent Dr. Vanicek, of the State Institute of Public Health at Prague, to organize this service.

It was decided to set up 22 stations for the distribution of penicillin, and on June 12 a meeting of the officers in charge of these stations was held at the State Institute under the chairmanship of Dr. Vanicek. At this meeting the need for some organization designed to bring pathology into close relation with clinical medicine became evident, and Dr. Vanicek and Dr. F. Pick, secretary of the European Association of Clinical Pathologists, who had recently arrived in Czechoslovakia from this country as a member of the first medical mission, were instructed to take steps for the formation of a society having this aim. At a second largely attended meeting held in Prague on July 10, with Dr. Vanicek in the chair, the whole question of the future organization of clinical laboratory work in Czechoslovakia was considered, and it was then decided to form a Czechoslovak Association of Clinical Pathologists and further that this should be a branch of the European Association. In Czech, as in all Continental languages, there is no term equivalent to the English "clinical pathologist"; the meeting decided to adopt the literal translation of "kliniky patholog."

The first general meeting of the new association was held at Prague on Oct. 18. Dr. S. C. Dyke, president of the European Association of Clinical Pathologists, was invited to be present, but owing to delay in transport he did not arrive until the day after the meeting. Over 100 medical men and women attended the meeting, at which there was a thorough and searching discussion of the future organization of clinical pathology in Czechoslovakia. In view of the fact that Dr. Dyke had arrived too late to attend the general meeting of the Association of Clinical Pathologists, a special meeting of medical men and women was called at the Prague Medical Institute under the chairmanship of Dr. K. Machácek, of the Ministry of classical scholar, an antiquarian, and a naturalist. Then there were Edward Wotton (1492–1555), M.D. of Padua and Oxford, the first English physician to publish a systematic treatise on natural history; and William Turner (d. 1568), M.A. Cambridge, and M.D. of Bologna or Ferrara and Dean of Wells, the first Englishman who studied plants scientifically. His *Herbal* marks him as the father of English botany. The Elects of the College of Physicians, Sir William Butts—who interceded with his royal patient, Henry VIII, both for Wolsey and for Cranmer—and others were regarded by their contemporaries as eminent physicians. In their busy professional lives they had little leisure for setting down the fruits of their experience, and what advances they made in the healing art went unrecorded.

The dividing line between physician and surgeon was not clearly drawn under the Tudors. By the Physicians Act of 1540 (32 Henry VIII) medicine was defined as comprehending surgery, and gave the physicians the right to practise surgery when and where they liked. Some of the surgeons practised physic, although this was forbidden by an Act of 1543 which stated: "No common surgeons may administer medicine outward . . . for although the most parte of the said craft of surgeons have small coonning, yet they woold take great soomes of money and doo little therefore; and by reason thereof they doo oftentymes impaire and hurt theyre patients, rather than do them goode."

Caius, as we know, lectured on anatomy, and the Barber-Surgeons enlisted the services of good physicians to teach their members both anatomy and surgery. One of these was Richard Caldwell, M.D.Oxon, F.R.C.P., who with Lord Lumley founded a surgery lecture, the Lumleian Lectures. The Barber-Surgeons' Company, to whom this was first offered, failed to take advantage of it, and the lectureship then went to the Royal College of Physicians.

Other physicians practised obstetrics as well as physic. George Owen (d. 1558), M.D.Oxon, physician to Henry VIII, Edward VI, and Mary, is said to have brought Edward VI into the world by performing Caesarean section on his mother. Owen was President of the College of Physicians in 1553 and 1554, and was the author of a treatise entitled "A Meet Diet for the New Ague set forth by Mr. Owen." (Fol. Lond. 1558.)

Under the influence of the Renaissance Thomas Linacre organized physicians into a fraternity, promoted their education on the lines of Greek thought, and established English medicine as a scholarly and learned profession. He received much help from his illustrious medical contemporaries and immediate successors. The value of this achievement must be measured by its after-fruits rather than by its immediate results in the advance of medical knowledge, though these were by no means inconsiderable.

Revival of Surgery

Many physicians, as we have noted, were still ecclesiastics. So at first had been many of the mediaeval surgeons, particularly among the Benedictines, until the practice of surgery by the clergy was forbidden by the Council of Tours in 1163. In 1279 a College of Surgeons under the patronage of St. Cosmas and St. Damianus, known as the Collège de Saint-Côme, was founded by Pitard, who had accompanied St. Louis to Palestine as his surgeon. It attracted many pupils, and the corporations of surgeons in London and Edinburgh were modelled upon it.

But mediaeval surgery was based largely upon tradition; surgical writings were reproductions of the classical or Arabian authors; and it was not until the Renaissance that surgeons dared to employ independent observation and reflection. Sir Hugh Lett[19] in a previous lecture has shown how the study of anatomy was revived and freed from stereotyped beliefs by Andreas Vesalius (1514–64) of Padua, how anatomy was studied and encouraged at Barber-Surgeons' Hall, and the contribution that Thomas Vicary made to this foundation of true surgery in his administration and teaching, and by his elementary textbook for apprentice-students entitled *A Profitable Treatise of the Anatomie of Man's Body*, which, unfortunately, was based upon the old treatises of Galen and others and did not include the new teaching of Vesalius. Vesalius's great work on anatomy was published at Basle in 1543, and as early as 1545 Thomas Gemini brought out a translation of Vesalius's *Epitome* entitled *Compendiosa totius Anatomie delineatio* with copperplate engravings copied from Van Calcar's woodcuts. It was dedicated to Henry VIII. In 1553 Gemini published an English translation of his Compendium made by Nicholas Udall, better known as the author of the first English comedy, *Ralph Roister Doister*. This manual was dedicated to Edward VI. The third edition, in 1559, was dedicated to Queen Elizabeth.

Thomas Vicary's work in uniting the Corporation of Surgeons with the Barber-Surgeons and in promoting the teaching of anatomy and surgery led immediately to progress in British surgery. First, as students were well taught by experienced surgeons, operative surgery became much more dexterous and resourceful. This led on to further advances. In lithotomy, improvements were made in the use of the staff and other instruments. A "radical" cure of hernia superseded the application of the actual cautery, operation for stricture of the urethra was improved, plastic operations were done, and ophthalmic surgery was taken to some extent out of the hands of quacks. Trephining was largely practised, even for persistent migraine. Philip William, Prince of Orange, is said to have been trephined seventeen times.

The Company of Barber-Surgeons undoubtedly raised the study and practice of surgery to a high level, organized professional teaching and standards, elevated the social status and general education of the surgeon, and opened a new era in observation and treatment of surgical maladies. Here the highest meed of praise is due to Thomas Vicary and his followers, Thomas Gale and William Clowes.

Conclusion

We have gone back together to the England of the sixteenth century and have tried to realize the times in which Thomas Vicary lived. We have seen his royal patients, bluff King Hal, the consumptive boy King Edward, the sallow-faced tragic Queen Mary, and the red-haired, beruffed, resplendent Queen Elizabeth, with "the body of a weak, feeble woman; but having the heart and stomach of a king—and of a King of England, too." We have met in Thomas Vicary's company the men he knew and who influenced him—the scholarly Linacre, the learned Erasmus, Dean Colet, Sir Thomas More, the saint and martyr, Sir John Elyot, and facetious Andrew Boorde; Sir Williams Butts and other Tudor physicians; and the surgeons, Thomas Gale and William Clowes—all, like Vicary, inspired by the Renaissance and labouring together to improve education, medicine, surgery, and public health so as to leave their country a better place than they found it.

At Vicary's side, in imagination, we have trudged through the ill-paved streets under the overhanging gables of the houses. We have witnessed the ravages wrought by the plague and the "sweating sickness." We have gone into the country, visited the pleasant manor houses, strolled in the flower-gardens, and seen something of the rural sports, the feasting, the jousting, and the maskers and morris-dancers. We have marked the changes brought about by the dissolution of the monasteries, the struggle to maintain the hospitals of London and the Colleges of Oxford and Cambridge, and noted the poverty and destitution which existed side by side with profusion and extravagance in high places. We have passed from mediaeval times into the Elizabethan Age. As Froude said: "Now it is all gone—like an unsubstantial pageant faded; and between us and the old English there lies a gulf of mystery which the prose of the historian will never adequately bridge."

Thomas Vicary lived, like us, in a state of transition, a time of unrest and of social upheaval, when old men dreamed dreams and young men saw visions. It was, as I have endeavoured to show, in medicine, surgery, and public health, not a time of building but of laying foundations well and truly on which a future edifice was to arise; not a time of harvest but a time in which the seeds of knowledge were sown. Linacre organized medicine and Vicary established surgery as learned professions. They thus opened the doors to the light of the Renaissance, brushed aside the cobwebs of the schoolmen, taught the value of independent thought, experiment, and observation, and rendered possible the epoch-making discovery of William Harvey, the investigations of John Hunter, and the triumphs of medical research which continue up to the present day. Equally, we have traced the beginnings of social medicine and public health in the enlightened writings of Sir Thomas More and his administration.

Health, at which Dr. Dyke, by invitation, spoke on "Clinical Pathology in England." Dr. Dyke spoke in English, with which the audience showed perfect familiarity, and the address was followed by a discussion.

The whole question of the future organization of the medical services of the Czechoslovak Republic is now engaging the lively attention of the medical community of that country, and there is the keenest anxiety to learn how medicine in all its branches has been developing in England during the years of separation of the two countries enforced by the war.

ROYAL MEDICAL FOUNDATION OF EPSOM COLLEGE

Annuity, Scholarships, and Grants

The Conjoint Committee of Epsom College will in February, 1946, award an annuity of £34 to a spinster daughter of a duly qualified medical man. Candidates must be not less than 65 years of age, and their annual income must not exceed £120 irrespective of help from the Royal Medical Benevolent Fund.

Educational grants will be also available in February from the Sherman Bigg Fund for children of either sex. These grants are not restricted to orphans or to members of any religious denomination, but candidates must be of public school age and in need of such help.

From the Eastes Trust grants are available for the relief of registered members of the medical profession of any age, their widows and orphans, and educational assistance for daughters or, failing them, sons of deceased male members, or full orphans, one or both of whose parents were members of the profession.

The Council of Epsom College will in March, 1946, award St. Anne's Scholarships to girls attending Church of England schools. Candidates must be fully nine years of age, and must be orphan daughters of medical men who have been in independent practice in England or Wales for not less than five years. The value of each scholarship depends on the means of the applicant and the locality and fees of the school chosen.

Forms of application for the vacant annuity, scholarships, and grants can be obtained from the Secretary, at the Secretary's Office, Epsom College, Surrey, and must be completed and returned by Jan. 18, 1946.

HELP FOR HOUSEHOLDERS IN CASE OF EPIDEMICS

The Minister of Health, in consultation with other Ministers, has considered the action which should be taken to assist households if infectious disease should assume serious epidemic proportions this winter. The Minister has primarily in mind the possibility of an influenza epidemic not requring admissions to hospital on a large scale, and the arrangements are framed accordingly. Steps have been taken to reinforce, so far as practicable, the defences against the introduction and spread of diseases from abroad, and the maintenance of the physical condition of the population so as to promote resistance to epidemic infections has been kept constantly in view by the Government; but the Minister thinks that local plans made in advance of a possible emergency will be a valuable additional insurance, which local authorities will wish to do their best to provide in conjunction with the Government Departments concerned. The main types of assistance which the Minister has in mind are in respect of doctors and nurses, help in the home, and provision of meals.

Doctors and Nurses

Arrangements have been made under which, in districts where the need is urgent, medical officers of the Services will give such help in civilian work as their duties permit. The War Office have also agreed to reinforce the civilian pharmaceutical services by the loan of a number of R.A.M.C. "other ranks" and V.A.D. members who are qualified pharmacists. Medical officers of health are being advised by the Minister's Chief Medical Officer on the methods of applying for help.

So far as nurses are concerned, the resources of the National Nursing Reserve, which is about to be set up, will be available. Authorities should also consider in what ways assistance can be given by the diversion or adaptation of existing services—e.g., health visitors and school nurses. The British Red Cross Society and St. John Ambulance Brigade will help in many areas, and in some it may be possible to enlist the services of former volunteer helpers at first-aid posts and rest centres to act as auxiliary nursing personnel.

Help in the Home

Welfare authorities have power to provide home helps under their general welfare powers, and domestic helps under Defence Regulation 68E, and plans should be made temporarily to develop these services as widely as the statutory authority permits. It may be possible to draw up reserve lists of those willing to serve in an emergency in these services. The W.V.S., the British Red Cross Society and St. John Ambulance Brigade, and other voluntary bodies will also be able to provide help in many areas. Generally the object would be that these services should operate without any delay on request from a doctor, a nurse, a health visitor, or a hospital; and that there should be some simple machinery for considering requests from other sources. The Ministry of Food and the Ministry of Education will be prepared, in an emergency, to facilitate arrangements on a payment basis for the provision of meals from British Restaurants and school canteens.

The Minister has consulted the headquarters of W.V.S., the British Red Cross Society, and the St. John Ambulance Brigade, and they have promised to help in the organization of these advance plans, and in the operation of them if this becomes necessary. An emergency of the kind contemplated would require the fullest exercise of local initiative and resource. It may be possible in some areas, where the Civil Defence services were closely knit, to reproduce wartime arrangements for mutual aid on a street basis, backed up by the local authority's resources as necessary.

A copy of the circular, which gives this information in detail and much general guidance for local authorities, has been sent by the Ministry to each medical officer of health.

MENTAL HOSPITALS IN WARTIME

The use, because of war conditions, of mental hospitals by the Emergency Medical Services of the Ministry of Health for the civilian sick may have helped to do away with some of the apprehension and suspicion with which they are regarded. This is one of the conclusions drawn by the Board of Control, in its 31st annual report,* from the fact that during the war years there has been a decrease in temporary and certified patients but an increase in the number of voluntary admissions to mental hospitals.

The steady increase in the number of voluntary patients has continued, and there are clear indications that the average period of stay in hospital has diminished. This change is due in part to the application of modern methods of treatment, but mainly, in the Board's view, to the fact that patients in recent years are being admitted to hospital at an earlier stage of the illness. The development of out-patient clinics has resulted in a wider appreciation of the work of the psychiatrist, psychologist, and social worker, both inside and outside mental hospitals. Many patients who hitherto feared to admit that they were ill are now ready to accept treatment.

Future developments recommended by the Board include more adequate facilities for diagnosis and treatment of both adults and children, with a wider range of contacts with schools, industry, the Courts, and the community generally. It hopes that such developments will be facilitated as a result of the inclusion of the mental-health service within the scope of the National Health Service.

Dealing with the considerable proportion of old people in mental hospitals, the report mentions the general belief that persons of 65 and over no longer find the comfortable place in the family circle which they enjoyed in the Victorian era. While this may be true there was actually a fall in the proportion of the admissions of old people in relation to the population in this age group at 1921 and 1931.

After-care for Ex-Service Cases

Further references are made to the scheme for providing after-care for members of the Forces discharged from special hospitals and centres on account of psychiatric disability. Arrangements were made early last year for the inclusion of merchant seamen. The total number of cases referred to the Board during 1944 was 2,651, but in addition many other ex-Service cases were brought to the notice of the Provisional National Council for Mental Health by Government Departments and voluntary organizations. Problems dealt with by the psychiatric social workers engaged in the scheme have been mainly those arising from the patients' mental condition, re-establishment in employment, family relationships, housing and furnishing difficulties, and financial worries. The year's experience of the working of the scheme indicates that it has afforded much-valued assistance to patients needing a specialized form of help which would not otherwise have been available.

At the end of 1944 the number of persons suffering from mental disorder notified as under care in England and Wales was 146,268 (males 62,518, females 83,750), a decrease during the year of 1,289 compared with a net increase of 39 in 1943. The average annual decrease for the five years up to 1944 was 2,182, compared with an average annual increase for the period 1934–8 of 1,691. Of the patients 87% were under care in mental hospitals provided by local authorities.

---

* For reasons of paper economy, the report is not being printed or put on public sale at present.

For all this we honour the Oxford humanists and Thomas Vicary to-day. Each in our own way, whether our gifts be great or small, must follow the high aims the Tudor pioneers set before us to maintain health, to prevent and cure disease, and to improve the lot of man.

PREVENTION OF HOMOLOGOUS SERUM JAUNDICE*

BY

J. F. LOUTIT, B.M.

AND

K. MAUNSELL, M.D.

Homologous serum jaundice, which has been reviewed several times recently (Memorandum of Ministry of Health, 1943; leading article, *B.M.J.*, 1944; leading article, *B.M.J.*, 1945), is being recognized with increasing frequency. It occurs 40 to 160 days after the introduction of foreign homologous serum into a recipient. This may be:

Accidental—during routine venepuncture with syringe and needle for blood samples for blood-sugar, B.S.R., etc., determinations or routine intravenous injections (arsphenamine, pentothal, etc.)—called "syringe jaundice." Traces of foreign blood are considered to have been left in the syringe and, through failure to clean and sterilize the syringe, this foreign serum gains access to the subject's circulation.

Deliberate—serum or plasma transfusion, prophylactic injections of measles and mumps convalescent serum or normal adult serum, and yellow-fever vaccination in which human serum is the suspension medium for the killed virus.

The prevention of homologous serum jaundice depends upon the circumstances of the introduction of the serum. In the "accidental" variety—syringe jaundice—adequate cleaning and sterilization of syringes and needles has been shown to reduce the incidence of post-arsphenamine jaundice practically to zero (Salaman *et al.*, 1944). The recommendations of the M.R.C. Syringe Sterilization Committee should be adopted: sterilization of all-glass syringes by dry heat (160° C.) for a minimum of one hour is the method of choice. If unsterile syringes only are available, although it has been recommended that the syringe and needle be withdrawn before the tourniquet is released (Shackle, 1945) to avoid sucking back of blood from the syringe into the vein when the tourniquet is released (Mendelssohn and Witts, 1945a), it is preferable by far that a needle only be used (Mendelssohn and Witts, 1945b; Darmady and Hardwick, 1945). When the introduction of serum is deliberate, prevention of homologous serum jaundice is much more difficult. The yellow-fever-vaccine problem was solved only by giving up the use of serum as a suspension medium. No satisfactory recommendation for the avoidance of homologous serum jaundice due to transfusion or to measles and mumps prophylactic sera has yet been made. MacCallum and Bauer (1944) have noted that it had been their practice to obtain supplies of normal human serum for use in the production of yellow-fever vaccine from a panel of donors whose state of health could easily be followed. The sera were always kept for a month before use in order to see whether any of the donors was incubating an infectious disease. Using such sera (apparently unpooled) no case of jaundice caused by the vaccine was reported. It was therefore our intention when collecting sera for measles prophylaxis to follow the donors for two to four months before issuing the sera for clinical use; but for transfusion purposes in the war emergency this was not possible.

MacCallum and Bauer's good results may have been due not to apparently healthy donors but to using unpooled sera. Whereas homologous serum jaundice often follows transfusion of serum or plasma alone or serum or plasma + blood, it appears to be uncommon after transfusion of whole blood alone, although cases have been reported (Beeson, 1943; Steiner, 1944). "It is, however, more difficult to be certain of the diagnosis in such cases. Batches of plasma and serum can be incriminated because multiple cases occur after their use; more or less homogeneous material has been given to many recipients. This does not obtain with whole-blood transfusion, which is a much more individual affair. Unless a single donor's blood on repeated occasions results in jaundice of the recipient, it is impossible categorically to aver that his blood carries a hepatotoxic agent; such a donor has not yet been reported" (*B.M.J.* leading article, 1944).

Investigation into Use of Single Sera

It was decided to investigate the results of introduction of single sera into a number of recipients and to compare the incidence of jaundice, if any, with that in a series of cases which had received only blood transfusion.

Collection of Sera.—Blood was drawn from 99 separate donors, under sterile conditions. 76 (Group I) of these donors had had no previous known attacks of jaundice; 15 (Group II) had had jaundice, apparently infective hepatitis, from some months to many years previously; 4 (Group III) had had homologous serum jaundice some months previously; and 4 (Group IV) were donors who had contributed four bottles of blood which had been the only material used for transfusion to a man with haematemesis who six weeks later developed jaundice. The blood of subjects in Groups I, II, and III (Table I) was allowed to clot at 37° C. and the clot to retract. The serum was pipetted off with a sterile Pasteur pipette and stored frozen until used a few days to a week later. The blood of the subjects of Group IV was collected in Nov., 1943, clotted at room temperature, and the serum Seitz-filtered and stored frozen until used for the tests 18 months later.

TABLE I.—*Follow-up of Donors and Recipients of Individual Sera*

Donors		Recipients				
				Complaints		
Group	No.	No. Tested	No. Followed	Jaundice	Nil	Miscellaneous
I (No previous history of jaundice)	76	462	444	0	433	Bilious attack 8 Skin rashes 3
II (Previous history of infective hepatitis)	15	91	82	0	79	Bilious attack 3
III (Previous history of homologous serum jaundice)	4	24	23	0	23	0
IV (Special cases)	4	25	24	0	24	0
Total ..	99	602	573	0	559	Bilious attack 11 Skin rashes 3

98 donors followed up 4 months:—94 no complaints; 3 bilious attacks; 1 skin rash; no jaundice.

Method of Administration.—On the day of use the serum was thawed out. A syringe and needle, sterilized by dry heat at 160° C. for two hours, was charged with the serum, and injections of 0.1 c.cm. of the serum were made intradermally with this syringe and needle into a series of four to nine, usually six, recipients.

Follow-up.—In the majority of cases the donors and recipients were followed up personally. At the end of 150 days each was asked by letter to answer whether he had had measles, scarlet

---

* A report to the Medical Research Council from the S.W. London Blood Supply Depot.

R.A.F. PHYSICAL MEDICINE ESTABLISHMENT

At 1, Sussex Place, Regent's Park, London, in bright surroundings free from any hospital atmosphere, the R.A.F. has a physical medicine establishment providing facilities for early treatment of cases of injury to muscle and joint structures. The main objects of the work there are: (1) to prevent the late and crippling results which follow damage to muscles and joint structures and often lead to a varying degree of permanent disability; and (2) the treatment of chronic conditions of muscles and joints which have followed injury, operations, and disease changes not adequately treated in the early stages. The department, which started with one room and one half-time Service-trained masseuse in October, 1942, is now giving about 7,000 treatments a month, and has ten masseuses and a radiographer. The majority of the cases fall into seven groups: (1) Minor strains of muscles, ligaments, and other joint structures. (2) More serious strains of muscles and sprains of other joint structures, causing partial or total incapacity. (3) Atonic and wasted muscles after injuries of all kinds, including after-effects of dislocations and fractures and certain types of early periarticular arthritis. (4) Adhesions, many cases of which are treated by manipulation to free the adhesions, followed by graduated muscular contractions for muscular wasting. (5) Fibrositis. (6) Early periarticular arthritis. (7) Early osteo-arthritis.

On Nov. 9 Princess Alice and the Earl of Athlone made a tour of inspection of the establishment, being received on arrival by Air Cdre. J. Kyle, Sir Morton Smart, and Squad. Ldr. B. Kiernander, who is in charge at Sussex Place. They were shown some of the treatment that the patients undergo—including exercises, massage, galvanism, graduated muscular contractions. They also saw typical cases, among them that of a Dutch air gunner whose right elbow had been shattered. The visit concluded with two films, one of them—exhibited for the first time—demonstrating how muscles may be made to react by electrical stimulus.

Reports of Societies

PLACENTA PRAEVIA

Three contributions on placenta praevia, giving the tabulated experience of this condition at three maternity hospitals over a number of recent years, were submitted at a meeting of the Section of Obstetrics and Gynaecology of the Royal Society of Medicine on Nov. 16. Prof. F. J. BROWNE presided.

Reduction of Foetal Mortality

Mr. C. H. G. MACAFEE (Royal Maternity Hospital, Belfast) based his remarks on 191 cases (including 24 private cases) from 1937 until Sept. 30 last. There were one maternal death (0.52%) and 42 stillbirths and neonatal deaths (22%). When the foetal mortality was corrected by the elimination of abnormalities, such as anencephalia, from the stillbirths and of gastro-enteritis from the neonatal deaths, it was only 18.8%. In an earlier series of 76 cases from 1932 to 1936 the maternal mortality was 2.6% and the foetal mortality 51.3%.

The two main objectives in dealing with placenta praevia were to reduce the foetal mortality without unfavourably affecting the maternal condition and to keep an open mind concerning treatment. One of the causes of foetal mortality in placenta praevia was prematurity. In the later years of the period under review the attitude adopted had been that placenta praevia was not an obstetric emergency which must necessarily receive active treatment on the first haemorrhage, and this attitude had much enhanced the infant's chances of survival by lessening the complication of prematurity. In this new series of cases approximately 40% of the stillbirths and neonatal deaths occurred in the first two years of the period. In 1944 there were only three such deaths, representing 16.6% of the cases, and in the first nine months of this year only one death (6.4%). The type or degree of placenta praevia had an important influence on treatment. Incidentally he pleaded for the removal from obstetric literature of the terms "lateral," "marginal," and "central," which were not consistently used by writers. The insertion of the cord in relation to the separated area of the placenta was important and accounted for a certain unavoidable foetal mortality. If the cord were inserted at the lower edge of the placenta where the separation occurred the child was unlikely to survive and often died from the initial haemorrhage.

Vaginal examination must be carefully considered. The decision as to when this examination should be carried out must be made by someone with experience, not by the junior resident medical officer. With a few exceptions a vaginal examination had been made in all cases in his series, but not until all preparations were ready for carrying out whatever treatment was most appropriate for the individual case. Therefore the examination had been postponed until the termination of expectant treatment. The cervix and vagina should, of course, be inspected by the speculum after the first haemorrhage. He submitted that vaginal examination was an essential part of treatment for the following reasons: (1) it was not possible to diagnose placenta praevia on the character of the haemorrhage; other causes of bleeding had been met with which would have been impossible to distinguish apart from vaginal examination; (2) the diagnosis of placent praevia should not be made unless the placenta had been felt in the lower uterine segment; and (3) it was only after making a vaginal examination that the type of placenta praevia and the best method of treatment could be decided. Mr. Macafee showed the following Table:

Methods of Treatment	No. of Cases	Stillbirths or Died	Per cent.
Artificial rupture of membranes ..	54	7	13·0
Artificial rupture of membranes and Willett's forceps	21	9	42·8
Version	23	18	78·3
Caesarean section	79	2	2·5
Breech	6	5	83·3
None	8	1	12·5

One maternal death followed a Caesarean section, and was due to a staphylococcal septicaemia—a maternal mortality rate for Caesarean section of 1.27%.

In the light of the excellent results recently published Mr. Macafee thought that as obstetricians they must revise their attitude towards the maternal and foetal mortality associated with placenta praevia. This mortality had been regarded as inevitable in the past; he believed it could be radically reduced, and that within ten years from now workers might be presenting results to the Section which would eclipse anything presented that night. He added that his own results were due to the collaboration of many individuals, including general practitioners, the hospital residents, the blood transfusion service, the anaesthetists, and, not least, the patients themselves. With more team work he felt that he could approach these cases with greater confidence.

Factors Making for Improved Results

Mr. LEONARD PHILLIPS (Queen Charlotte's) said that in 1933 at his hospital a system of allocation of cases was organized whereby any member of the staff could have in his care the particular type of case in which he was most interested, and it became his privilege to deal with cases of placenta praevia over a period of about five years. During that time 143 consecutive cases were treated. The maternal mortality rate in placenta praevia had been considerably reduced over the last ten or fifteen years. Formerly 10 or 15% mortality was quite common; 5% was now more usual, and there were series of cases which showed much lower mortality rates than that. The principal procedures had not changed much during twenty-five years and the conditions surrounding the cases were very much the same, yet the results had improved.

The first important factor responsible for improvement was that cases were sent into hospital in a better condition. Years ago any general practitioner felt himself able to deal with any case of placenta praevia, even under the most disadvantageous conditions, in the patient's home. Now the patients were sent into hospital, usually after the first warning haemorrhage. A second factor was the increased use and better technique of blood transfusion. Mr. Phillips placed this as the principal cause of the good results in his own cases. With a modern well equipped and staffed general hospital deaths from haemorrhage should be very rare, and if a patient arrived in good condition and died of haemorrhage from placenta praevia it should be taken as a personal reflection.

Another factor in improvement was the extended use of Caesarean section. He recalled a meeting at the Royal Society of Medicine twenty-five years ago when Dr. Herbert Spencer fever, diphtheria, jaundice, typhoid, or mumps in the past or recently, and also whether in the previous six months he had had bilious attacks, and if so when. The results of the follow-up are shown in Table I.

No jaundice occurred in any of the recipients or any of the donors during the period of follow-up. Eleven bilious attacks and 3 skin rashes were reported among the 573 recipients who answered the questionary, and 3 bilious attacks and 1 skin rash among 98 donors. Bilious attacks and skin rashes are very non-specific terms, and were included in the questionary only because they so often figure as complaints by people in the prodromal stages of hepatitis. It is probable that both the skin rashes and the bilious attacks were in this instance non-specific, because there was no appreciable difference in the incidence of such complaints in the recipients who might be considered exposed to the risk of homologous serum jaundice and the donors who were not, and because each of the 14 recipients who reported these symptoms had received different sera; thus, of the four to nine recipients of each serum, in no case did more than one complain of symptoms. It is notable also that the 105 recipients of serum from previously jaundiced cases, whether infective hepatitis or homologous serum jaundice, did not develop these non-specific symptoms more frequently than those who had received serum from donors who had not previously had jaundice.

Follow-up of Blood Transfusion Cases.—During the last five years subjects who have received whole blood or concentrated red cell suspension have been followed up carefully, at intervals of a few days to a few weeks up to two months or more by Dr. P. L. Mollison and ourselves. The object of this follow-up was to determine not the incidence of delayed post-transfusion jaundice but the survival of the blood transfused. Nevertheless it is probable that frank cases of jaundice would have been noted or learnt of during the periodical visits. In this way 213 cases were followed up. In Table II the cases and the period of follow-up are charted. In this series there was one frank case of jaundice; but this patient had all the stigmata of infective hepatitis. She was a girl of 16 who had been transfused for anaemia following appendicectomy. She developed jaundice within a day or two of her sister, nine weeks after leaving hospital and 13 weeks after transfusion. Three other siblings had had jaundice three weeks previously, and infective hepatitis had been rife at the school where one of the siblings attended. Another patient developed severe malaise and anorexia eight weeks after transfusion. She had been transfused with the blood of a man recently recovered from infective mononucleosis. She had no definite physical signs, but a blood count showed a slight lymphocytosis with the presence of a few primitive lymphoid cells. The Paul–Bunnell test was negative. This may have been a case of hepatitis without icterus.

Table II.—*Follow-up of Selected Cases Receiving Blood Transfusion*

Follow-up (days)	No. in Group	Jaundice or Hepatitis
60 to 69	96	0
70 „ 79	28	0
80 „ 89	7	0
90 „ 99	29	1*
100 „ 109	7	0
110 „ 119	11	0
120 „ 129	12	0
130 „ 139	14	0
140 „ 149	6	0
150 +	13	1†

* Diagnosed as infective hepatitis. † Diagnosed as ? hepatitis sine ictero. (See text.)

In addition to the previous follow-up, since 1942 we have been looking for cases of hepatitis following transfusion of whole blood alone. Only two suggestive cases have been found. One was the case quoted above—that of a man of 49 with haematemesis who was transfused on July 30 and Aug. 1, 1943, on each occasion with blood from two donors. On Oct. 14—45 days after the last transfusion—he developed prodromal symptoms of hepatitis; jaundice followed two days later. He knew of no contact with other cases of jaundice. The 4 donors (Group IV, Table I) who contributed the blood for his transfusions were interviewed. None of them had ever had jaundice or had recently been in contact with cases of jaundice. The other case was also that of a man with haematemesis, who in the course of two weeks received blood from 52 donors, all of whom could not be traced. He developed a mild jaundice eight weeks after the last transfusion.

Discussion

The follow-up of the cases transfused with blood alone was too short to pick up all potential cases of homologous serum jaundice. It confirms, however, the impression that this jaundice occurs only rarely after transfusion with whole blood. This is probably due to the fact that cases receiving transfusions of blood alone get homologous material from a few donors only, though it is now becoming more common for massive transfusions involving many donors to be given; this is exemplified in the above patient who had blood from 52 donors.

The present experiments with 99 individual sera suggest that these sera are as safe as individual bloods. The dose given—0.1 c.cm.—was small, but, with known icterogenic sera, doses of this order are no less icterogenic than doses of hundreds of c.cm. (MacCallum and Bauer, 1944; Bradley, Loutit, and Maunsell, 1944).

These results are in striking contrast with those of Janet Vaughan (personal communication, 1945) and others, which suggest that homologous serum jaundice following transfusion of pooled blood plasma or serum, with or without whole blood, occurs in about 10% of cases. The pooled plasma and serum used in these transfusions were prepared by mixing material from several hundreds of donors, Seitz-filtering the mixture, and, in the case of many of the icterogenic batches reported, drying *in vacuo*. It has been postulated that the icterogenic agent is a virus. If this be so, it could certainly pass the Seitz filter and presumably survive the drying process; it may even be stabilized thereby. If it be a virus, it is unlikely that it would be inactive in preserved whole blood. Therefore, if it be present in whole blood and yet blood transfusions rarely cause homologous serum jaundice, it can be present only in very occasional bloods. In such an instance the pooling of many plasmas and sera to make therapeutic or prophylactic sera is ill advised, as one icterogenic plasma or serum may contaminate the whole pool. It has even been suggested (Andrewes, 1944) that dilution of a virus may increase its virulence.

It can be recommended, therefore, that sera for prophylactic use should be individual sera. For transfusion therapy it is not practicable to obtain more than 200 to 300 c.cm. of plasma or serum from any one donor. This amount is inadequate as a therapeutic unit, and has the disadvantage in the case of single donors of having unwanted iso-agglutinins. Serum and plasma for transfusion purposes should in our opinion be obtained from two or three or at most ten donors, so selected that the iso-agglutinins are neutralized by the corresponding iso-agglutinogens present in plasma, by corresponding red cells, or perhaps by the purified "group-specific substances."

Summary

Each of 99 individual sera was injected into an average of 6 normal recipients. No case of homologous serum jaundice was detected within 150 days.

No case of frank homologous serum jaundice occurred in a selected series of 213 blood transfusions. Two possible cases of homologous serum jaundice, following blood transfusion alone, are recorded.

It is recommended that for therapeutic and prophylactic sera the serum used should be from a single individual or, at the most, from a few persons only.

We are grateful to Dr. P. L. Mollison for allowing us to use many of his follow-up records, and to physicians and surgeons of St. Helier Hospital, Carshalton, for notifying us of cases of homologous serum jaundice.

declared that he had treated many cases of placenta praevia and had never found it necessary to do a Caesarean section. At the same meeting, however, Prof. Blair-Bell said that in nearly all the cases of placenta praevia that came to him he did carry out Caesarean section. To-day Mr. Phillips thought that it would be difficult to find any consultant of experience who could say that he had not done a Caesarean section. His own feeling was that all cases of complete placenta praevia ought to be so treated, as well as a number of others with conditions he described. Another reason for the extended use of Caesarean section nowadays was the different attitude towards the child. They still believed that the child should not be considered at the expense of the mother, but it was very difficult to say sometimes whether Caesarean section was at her expense or not. In these days of single children and spaced families, where very often a placenta praevia baby was one which came after ten years of married life, or where the mother herself demanded that Caesarean section should be done, the position was difficult, and they were all aware of the psychological damage that might be done to the mother as the result of a lost baby. Moreover, they were now very much better at dealing with premature babies.

Mr. Phillips then showed an analysis of his 143 cases. There had been two maternal deaths, both in the marginal type of case; there were no deaths in the lateral type or in the complete placenta praevia type. The stillbirth rate was about 50%.

Method of Treatment	Number of Cases	Maternal Deaths	Stillbirths
Artificial rupture of membranes and binder	54	0	21
Bringing leg down	15	0	14
Caesarean section	9	0	0
Caesarean section with plugging ..	6	0	1
Plugging with rupture of membranes and binder	59	2	39

Looking back on these cases he saw that he had made a number of mistakes. He no longer treated these cases as emergencies, he left them alone and waited until they bled, and if they bled heavily he then dealt with them along these lines. In another series of cases he thought he would do less plugging and more Caesarean sections.

Antepartum Haemorrhage in General

Miss **JOSEPHINE BARNES** (University College Hospital) dealt with the subject in relation to the general problem of antepartum haemorrhage. She said that there was a great deal of confusion over the classification of cases of antepartum haemorrhage and also the diagnosis and classification of placenta praevia. From 1927 to the end of 1944 there were 538 cases of antepartum haemorrhage admitted to the obstetric hospital at University College. Of this number 21 were delivered outside the hospital. The remaining 517 were classifiable as follows:

Placenta praevia	140
Accidental antepartum haemorrhage	73
Antepartum haemorrhage of uncertain origin	285
Antepartum haemorrhage from extraplacental lesion	19

A case was not accepted as being one of placenta praevia unless the placenta was either felt from below or was found in the lower uterine segment after section. Among these 517 cases the maternal deaths numbered 14 (2.7%) and the stillbirth or neonatal mortality (520 infants) was 192 (36.9%). Among the cases of placenta praevia alone the maternal mortality was 2.9% and the stillbirth or neonatal mortality rate 52.1%.

She went on to discuss the various methods of treatment. In cases of placenta praevia the methods of treatment adopted and the proportion of fatal results were analysed in the following Table:

Method of Treatment	No. of Cases	Maternal Deaths	Foetal Deaths
Caesarean section	38	1 (2·6%)	7 (18·4%)
Bringing down a leg	39	0	38 (97·4%)
Willett's forceps	36	2 (5·6%)	17 (47·2%)
Artificial rupture of membranes ..	11	0	4 (36·4%)

The maternal mortality occurred in what was known, according to the University College Hospital classification, as the second of the four degrees of placenta praevia. Like Mr. Macafee, she contended that classifications like "marginal," "lateral," and so forth should be set aside.

PLASTIC SURGERY

At a meeting of the Section of Surgery of the Royal Academy of Medicine in Ireland on Oct. 12 Mr. A. B. **CLERY** emphasized the necessity for an adequate case history in all conditions requiring plastic surgery. The cosmetic result was often as important as the functional result in the surgery of the face. All operations should be regarded as individual procedures and should not be stereotyped. He preferred general anaesthesia to local for large skin grafts or for operating on big scars, and used it exclusively in children; the intratracheal tube was necessary in oral surgery. With local analgesia premedication should be sufficient to ensure tranquillity in the patient; the local analgesic should be injected under the skin before making the injection along the line of incision. Deeper tissues could be infiltrated with a half-strength solution. Chemotherapeutic substances, such as penicillin and the sulphonamides, were only adjuncts to good surgery. Special precautions should be taken to avoid sepsis in operations in the oropharynx. Delicate instruments and very fine ligature material should always be used to avoid tissue trauma. There should be no tension on the immediate neighbourhood of the skin incision; and flaps should be well relaxed. When tension was unavoidable it should be widely dispersed. Deep relaxing sutures, tension bows, and pre-operative massage were valuable.

Types of Operation

The local advancement of flaps after resection was particularly useful in cases of hare-lip, birthmarks, moles, and the smaller scars. The lower lip was well reconstructed by rotation of the upper lip into the lower after a V section and wide undercutting. The main difficulty in utilizing the same operation for the upper lip was that the nose became compressed. To avoid this Mr. Clery advised the excision of segments of the skin of the cheek.

In cases of facial injury, because of the very good blood supply in this region, much débridement was not needed; sutures should be of fine nylon. If there was much tissue loss in the cheek region it might be advisable as a primary procedure to suture the mucosa to the skin in order to cut off sepsis; at a later stage plastic repair could be effected.

Keloid scars should be excised, and the area treated with a three-quarter erythema dose of *x* rays. In the repair of eyelids, neighbouring tissues might be advanced and utilized by undercutting and suturing; inlay skin grafts could be employed sometimes. For repair of the nose a modification of the old Indian forehead operation could be used, but if the forehead was scarred a tube graft from the abdomen might be transferred to the face via the wrist. The modern tendency was to use full-thickness skin grafts in rhinoplasty; these must be free of fat, of the exact size, accurately stitched, and kept under a pressure equal to 30 mm. of mercury for fourteen days. Unlike full-thickness grafts, split skin grafts could survive in the presence of sepsis and could be used on granulating areas—for instance, burns.

The annual general meeting of the Association of Anaesthetists of Great Britain and Ireland was held under the presidency of Dr. A. D. Marston at the Royal College of Surgeons of England on Oct. 31 and was attended by over 100 Fellows and Members. The business meeting took place in the afternoon and was followed after tea by three films demonstrating various anaesthetic techniques. A very successful dinner was held in the College in the evening, at which Sir Alfred Webb-Johnson, P.R.C.S., was the guest of honour. Next morning members attended operating sessions which had been arranged at the Middlesex, the Royal Cancer, St. Thomas's, and Westminster Hospitals.

G. Neubauer (*Arch. Dis. Childh.*, 1945, **20**, 81) examined 36 cases of cardiac complications among 602 cases of scarlet fever between August, 1943, and August, 1944, with the following results: 29 cases presented as myocarditis, 2 as partial auriculo-ventricular block, 4 cases as endocarditis, and 1 died of auricular fibrillation.

EAR DISEASE IN CHILDREN*

BY

D. RITCHIE PATERSON, F.R.C.S.Ed., D.L.O.

Ear disease with consequent deafness is so prevalent that it is a subject of great moment, whether considered from the standpoint of the medical affection or from that of economic loss to the community. Ear disease is no longer regarded with indifference, and the importance of conserving the hearing sense is generally recognized.

It is my belief that there are few more urgent problems than this in public health. In no other department of medicine is the effect of bad hygienic environment so evident. When good housing conditions give general sanitary science a fighting chance a reduction may be expected in upper respiratory and alimentary disease, of which middle-ear infection is such a serious complication. Meantime much of our treatment must be of a surgical nature, requiring not only knowledge of general surgical principles but an ever-present consciousness of the importance of the hearing sense. A prolonged period of emotional disturbance, and a life fraught with daily frustrations which only a most robust mentality can surmount, are the portion of a deafened individual. I feel that in many cases prompt attention to inflammation in the middle ear in its early stages would save the hearing, and in some few cases the life of the patient. We are constantly seeing patients with old-standing chronic suppuration in the middle ear who are irrevocably maimed by deafness. These cases are still too numerous among our school-children, and I would plead for more frequent resort to operative treatment in chronic ear suppuration in order to preserve the most important way into their minds—namely, the hearing sense. We have also seen those terrible catastrophes which follow intracranial complications of otitic origin.

Speech and hearing are indissolubly linked together. The "oo-eh" sound expressive of discomfort does not long remain alone, and within the first few weeks of life a number of different sounds expressive of comfort or discomfort can be noted. Babbling appearing within the first three months is characterized by perseveration—for example, "ba, ba, ba"—and the infant derives great satisfaction from this preliminary to speech. Possibly he senses, by feeling as well as by hearing, this new-found control over his vocal organs, for congenitally deaf children may babble just like those with normal hearing. During the second six months of life imitation becomes noticeable; but the child does not learn speech like a parrot, and the babble-word becomes speech when he subjectively connects some meaning with the word—for example, says "Mama."

About the beginning of the second year the one-word sentence appears. He offers the paper and says "Dada," or points to his mother's shoes and says "Mama."[1] About the middle of the second year he suddenly realizes the meaning and purpose of speech, and that everything has a name[1]; for example, he points to objects and says, "That! That!". As he learns inflexions he says, "That? That?"

Altogether this is a period of great mental development. I do not wish to go into this subject further than to emphasize that in the speech and language development of the normal child the essential processes are first hearing, then learning to imitate and to understand, the spoken word—accurate hearing of the whole of the words being an indispensable requirement. Just as the child in learning to read must scrutinize each letter carefully, so, to speak, he must hear every one of the complex tones which make up the pattern of speech. In the absence of hearing the understanding of words, speech, reading, or writing cannot develop naturally, and other ways in, through the eye and through touch, have to be found. Even acquired deafness, if severe and occurring before the fifth year, almost always destroys speech. Deafness occurring later produces a partial atrophy of speech, and even in adults the voice becomes monotonous and pronunciation imperfect. Auditory acuity and auditory memory are often found to be subnormal in children who show reading or writing disability.

Let us consider for a moment what bearing the anatomy of parts has upon disease of the middle-ear cleft.

Anatomy

By the ear, in a surgical sense, we mean not only the outer ear, or auricle and meatus, but also the middle-ear cleft, which extends from the Eustachian tube opening, behind the nose, by way of the Eustachian tube to the middle ear proper, thence by the aditus to the mastoid antrum and surrounding cells. It will be remembered that the temporal bone is developed from three parts: (1) the squamozygomatic, (2) the petromastoid, and (3) the tympanic ring.

The *petromastoid* is the portion which carries those parts essential to the auditory and vestibular mechanisms, and in addition it carries the bony parts of the Eustachian tube, the inner wall, and most of the roof and floor of the tympanic cavity, and also the mastoid antrum and its cells. It is important to realize that the roof of the tympanic cavity and mastoid antrum is also the base of the skull, and that in this situation a very thin plate of bone separates those parts from the meninges. The only portions of this, the middle-ear cleft, which are not formed from the petromastoid bone are a small part of the roof of the tympanic cavity, formed from the squamozygomatic bone, and the outer wall of the tympanic cavity, formed from the tympanic ring with its drum membrane. The drum membrane, therefore, is the only non-rigid wall of the middle-ear cleft, but it is of practical importance to remember that in the infant the tympanic membrane is relatively thicker than in the adult.

From these developmental facts it follows that there are two situations where different components meet—namely: (1) in the outer wall of the roof of the meatus—the squamopetrous suture; and (2) a vertical suture behind the tympanic ring—the squamomastoid suture. These sutures are important from a surgical point of view, since, until their closure one or two years after birth, cartilage remains in the neighbourhood, and, further, venous channels which persist throughout life traverse these routes.

The middle-ear cleft of the infant bears certain features which suggest its early predisposition to disease. First, it is lined by an outgrowth of the hypoblast of the upper air-passages, similar to the lining of the pharynx. It is this continuity of surface which is mainly responsible for the frequent development of middle-ear inflammation as a sequence of disease in the pharynx. Secondly, infection can pass from the pharynx, along the middle-ear cleft, more readily in infancy. The Eustachian tube in the child is much shorter than in the adult, and, further, the calibre of the tympanic end of the bony tube is as large as in the adult; hence in the child the whole canal is much shorter in relation to its width. The two portions—membranous and bony—are more nearly in the same straight line than in the adult; therefore the canal has no bend on it at the isthmus as in later life. Another point to notice is that the tube is almost horizontal in direction, so that while in the adult the pharyngeal orifice is on a lower level than the middle ear, in the child it is almost on the same plane as the latter structure.

It will thus be understood that extraneous material can find its way easily into the tympanic cavity of the child. On the other hand it is *highly probable* that the complicated mechanism formed by the chain of ossicles and folds of muco-periosteum over these little bones will prevent easy egress for extraneous materials, and, moreover, any blockage to the normal exit of the mucous secretion of the cavity will be followed by putrefactive changes in the retained secretion. This may be of little account in children fed at the mother's breast, but may be of considerable importance where heterogeneous materials are fed to the infant, and also where sterilization of that material is imperfect.

It should be noted that lymphoid tissue is found in abundance in relation to the tympanic exit (Eustachian tube), and, as in the case of lymphoid tissue in other parts of the body, this tissue predisposes to infection in the neighbourhood. It is universally recognized that infected adenoids are the most frequent cause of suppuration in the middle ear, especially in children.

Pathology and Aetiology

In infants infection of the middle ear is nearly always from the nasopharynx, either by direct extension or possibly by

Correspondence

Medical Future of the Colonies

Sir,—It is to be hoped that the leading article in the *Journal* of Nov. 17 on the medical future of the Colonies will arouse interest in the profession, and particularly among its younger members. I cannot pretend to be an authority on such matters, but for two years during the war I was consulting surgeon, East Africa Command, and in that capacity travelled widely in Kenya, Uganda, Somaliland, Abyssinia, Mauritius, and the Seychelles. I also visited Madagascar twice. These journeys gave me some idea of the immensity of the problems which face colonial medical services and of the difficulties which beset the medical officers belonging to them. Also, at the invitation of General Van Hoof, Director-General, Medical Services, I made a fortnight's tour of the Central Provinces of the Belgian Congo, and might have gone much further had not difficulties of air transport back to Kenya prevented this. I was much impressed by the efficiency of the medical services in that region—more efficient than our own because, so far as I could judge, much more money was available and also because the natives were under a far stricter medical discipline than is encouraged in British possessions.

The chief advantage gained by a doctor from colonial medical service is a unique opportunity of studying disease in all its forms; the chief satisfaction which he gains is that he can achieve so much by his own personal endeavours. The chief disadvantage is that he is cut off from association with other doctors, and completely separated from the great centres of learning which are found so close at hand in civilized countries. True, the bigger towns have their medical societies; in Nairobi, for example, there is a vigorous branch of the B.M.A.; but doctors in remote places are utterly without such contacts. If the best men are to be encouraged to make their careers in such a service frequent opportunities to refresh their knowledge must be provided. Opportunities to return to England for courses of instruction must be much more readily available than hitherto. It is not only in England that such postgraduate study need be sought; Johannesburg and Capetown already play their part in such training. And in Central Africa at Kampala in Uganda is Makerere College and its medical school (Mulago), which is devoted to the training of African medical students. The Colonial Medical Service have wise plans to develop this.

The needs, as it seems to me, are money and more staff, and it is to this latter point that I venture to draw attention. Splendid work is being done there and the opportunities for study are unique. No young doctor of first-class ability could fail to benefit from spending some time as a member of the staff of Mulago. But if he goes there, must he go for ever? Will his own or some other teaching hospital forget him because he has gone? Will such distant absence cause him to miss a vacancy on the staff at home? Now, if a really close liaison between Mulago and the teaching schools of this country can be established, so that to have held a post there for a period shall count strongly in a man's favour, then certain advantages will accrue. It should be possible not only to develop further the training of Africans as doctors but to establish, thus helped by an enlarged and varying staff, a readily accessible postgraduate centre for the medical services of Africa—both native and European.—I am, etc.,

London, W.1. R. Ogier Ward.

Sir,—The leading article on the medical future of the Colonies contains statements and makes assumptions which cannot be allowed to pass unchallenged.

Conditions vary so greatly in different parts of the Empire that generalization is hazardous. The article in question is obviously written from a West African view-point, and many of the defects, described as productive of that popular bugbear, "the feeling of frustration," are certainly not universal. And, to judge by your correspondence columns, this feeling of frustration is not unknown in the medical services of the Navy and Army.

As manifested by "grousing," the feeling of frustration is, moreover, by no means restricted to the medical services in the Colonies. But it is almost restricted to those who, lacking resources in themselves, are quickly disgruntled when deprived of the amusements—cinemas, public houses, and dances—to which they have been accustomed. The innumerable objects of interest by which they are surrounded in the Tropics have no appeal for them. Such persons are unsuitable for colonial service. Unfortunately, the notorious difficulty of getting rid of officials in a public service ensures their remaining in it, to poison the minds of younger officers. For, strange to relate, the very last thing these men desire is release from the service of which they have so much to complain. The removal of the difficulty in dispensing with the services of such undesirable officials is one of the most urgently needed reforms.

The familiar misstatement that what "can be done in war can likewise be done in peace" finds a place in the article. One had thought that this fallacy had long been exploded. The improved physique and mental alertness of the African, to which reference is made, was achieved by extremely generous rations (much of which was wasted) provided at the cost of severe shortage of food, amounting in at least one instance to famine, for the civil population. The response of the African to good food and living conditions is no new discovery; it was always to be observed in the K.A.R. and police. But the bald fact is that not enough food is produced in tropical Africa to provide adequate rations for all; to increase that production is the chief preoccupation of Governments.

The "raising of the standard of health of the indigenous populations," so greatly to be desired, involves much more than a "highly efficient medical service." The whole mode of life of many of these people will have to be changed "radically" but not "rapidly." Methods of cultivation, water supplies, communications, restoring the fertility of the soil, and many other questions are involved. Had those critical visitors to Africa enjoyed the advantage of observing what has, in fact, been accomplished in these directions during the past 25 years they would not, perhaps, have been so ready to find fault. Further, it may be remarked that before the war there were communities in Europe where the standard of life was little, if at all, in advance of that in tropical Africa, and must now be definitely below it.

It is true that the medical departments in many African colonies are understaffed, but figures showing the proportion of doctors to population are grossly misleading, unless accompanied by information on the number of such persons to whom European medical aid is acceptable. The appointment of additional specialist officers will avail nothing until the number of district medical officers has been greatly increased and there has been a general advance in civilization. For it is on the district M.O. that the rapid expansion of other departments has thrown such a great burden of extra work.

Changes of station are already frequent enough to cause dissatisfaction, especially among the married, and it is not easy to understand how more frequent upheavals would increase "the possibility of having one's wife and family with one." Lastly, in suggesting short-service commissions of five years "with a reasonable gratuity at the end," has the heavy expenditure by Government on the preliminary training of M.O.s in tropical medicine been remembered? Even Governments are entitled to expect an adequate return on their money.—I am, etc.,

Boscombe. J. B. Davey (formerly P.M.O., Tanganyika).

National Research into Tuberculosis

Sir,—In your second leader, "Triumph against Malaria" (Nov. 10, p. 653), tribute is paid to the fine example of British team work and organization which led to the discovery of a new antimalarial compound. The loss of quinine led to a search by British scientists for a new drug effective against malaria parasites, and it is now revealed that such a drug has been found.

In the same issue Sir Howard Florey (p. 635) states that much attention is being applied to the possibility of discovering an antibiotic which will be effective against tuberculosis. This letter is written in the hope that British medicine will do a little more—namely, establish a research unit with the sole respondirect droplet infection along the Eustachian tube. According to the experience of the majority of otologists blood infection is very rare, but it is by no means impossible; and it is more likely to occur in the young subject and in relation to those parts where cartilage is still present. *Primary* infection by micro-organisms from the external meatus is also uncommon, and would occur only through rupture of the drumhead from fracture accompanying injury to the skull or entry of a foreign body.

Since infection has its beginning in the nasopharynx, ear disease is commonest in those with poor anatomical types of pharynx; further, it is found that the micro-organisms responsible for the inflammatory exudate found in the middle ear are those types occurring in the pharynx—namely, *Streptococcus mucosus*, pneumococcus, other types of streptococcus, staphylococcus, tubercle bacillus, etc.

It has been seen that the presence of adenoid growth in the nasopharynx is of primary importance in disease of the middle ear. Even although adenoid tissue is not grossly infected, it may give rise to various pathological changes in the middle ear.

1. The Eustachian orifices may be blocked and the aeration of the middle ears prevented, so that the air in the tympanic cavities becomes absorbed and the tympanic membranes, lacking the equalizing-pressure effect of the column of air from the Eustachian tubes, are pushed inwards (producing the condition known as indrawn tympanic membranes). This in turn may give rise to the formation of adhesions, the improper functioning of the parts, and hardness of hearing.

2. Blockage of the normal exit, resulting in imperfect drainage of the mucus from the middle-ear cleft, may cause the tympanic cavity to be filled with more or less sticky fluid, and this may give rise to an even more pronounced deafness.

3. It should be noted that a similar condition to the last-mentioned would occur from the outpouring of an extra quantity of mucus, the result of a comparatively mild infection from the nasopharynx.

4. *Tuberculous Infection of the Middle Ear.*—This condition may arise by direct spread of the infection along the lymphatic arrangement in relation to the Eustachian tube or by droplet infection. It is just possible that it may also occur at the junction of cartilage and bone, in certain situations in the middle ear. The little yellow tubercles may be found studded over the muco-periosteum of the middle ear, and on breaking down may give rise to multiple perforations of the tympanic membranes. Remembering the points which I have brought forward concerning the anatomy of the Eustachian tube in the infant, it will be realized that use of tubercle-free milk marks an advance in the treatment of ear disease. When infection does occur the enlargement of the posterior chain of the lymphatic glands in the adenoid infection, or the anterior chain in the neck in tonsillar tuberculosis, usually directs attention to the pharynx, with the eradication of the primary focus before the middle ear is affected.

5. *Acute Suppurative Otitis Media.*—This is one of the commonest aural conditions that not only the otologist but the general practitioner is called upon to diagnose and treat. It arises in very many cases from an acute infection in the throat, and while it is usually seen during the course of the exanthemata (especially in measles and scarlet fever) it is hardly less common during influenza, acute coryza, and certain epidemics of gastro-enteritis. There is the invasion of the middle ear by virulent micro-organisms—e.g., *Str. mucosus* or *Str. pyogenes*—with destruction of the mucosa and the formation of pus. In the early stages petechial haemorrhages may be seen in the mucosa, and the exudate is sero-haemorrhagic but rapidly becomes purulent. In some influenzal cases, however, it is frankly haemorrhagic. The tympanic membrane, the only membranous wall to the cavity, ruptures early in the course of the disease if the virulence of the infection is great and if the drainage is interfered with by swelling of the mucosa. The mastoid antrum and cells may become infected and, an acute mastoiditis resulting, at any moment the disease may spread to neighbouring vital organs, with far-reaching consequences and disastrous results.

The course of suppurative otitis media is subject to much variation, and fortunately, like inflammation elsewhere, resolution may occur. It may run a fairly acute course for a few days and rapidly clear up, drainage taking place through the Eustachian tube. Again, rupture of the tympanic membrane may result in such good drainage of the middle ear that rapid recovery and healing of the tympanic membrane follow. On the other hand, the acute phase may pass into a chronic condition. The perforation does not heal up, and secretion from the chronically inflamed lining membrane escapes through it. Or the secretion may become inspissated, obstruct drainage, and thus lead to the condition flaring up as before. This is especially true of *Str. mucosus* otitis media—possibly the most insidious of all infections of the middle ear.

In *chronic inflammatory conditions of the middle ear*, especially in children, there is a tendency to the formation of granulomatous masses, of polypi, or, later, of cholesteatomatous material. So long as the inflammation, acute or chronic, persists, complications may arise. These are (1) acute mastoiditis, (2) extradural abscess, (3) sinus phlebitis, (4) leptomeningitis, (5) cerebellar and cerebral abscess. These complications depend upon the direction in which the infection spreads from the middle ear. From the mastoid antrum, the posterior end of the middle-ear cleft, the inflammation may spread outwards, upwards, or backwards. If outwards, a periostitis is set up and a mastoid abscess may present itself. This occurs most often in children. This abscess may remain in the locality of the mastoid or, passing downwards, may appear under the deep fascia below the mastoid process. If the spread is upwards from the antrum or middle ear, necrosis of the thin bony roof occurs, or the process may result in thrombosis of the osseous veins. In either case extradural abscess, leptomeningitis, or cerebral abscess may result. If the direction of spread is backwards an abscess may form round the wall of the lateral blood sinus, the wall itself may become inflamed, septic thrombosis may occur within the lumen, the leptomeninges of the posterior fossa may be infected, or, lastly, a cerebellar abscess may form. Should the infection spread inwards the labyrinth is involved and the delicate mechanisms—cochlear and vestibular—are destroyed. The infection passes readily from here along the internal auditory meatus to the cranial cavity, giving rise to a generalized purulent leptomeningitis.

Symptoms and Signs

A careful assessment of the patient's general condition is just as important here as in other specialties. The history-taking and as much of the examination as possible should be conducted in daylight. Time is not then likely to be lost in the treatment of certain occasionally concurrent manifestations of disease—icterus, for example. There are complications of cardiac, renal, and blood systems which are called more readily to the surgeon's mind when the preliminary examination takes place in good daylight.

To the infant "all that is painful is evil, while all that is pleasant is good." Crying is practically the only means by which the infant can indicate discomfort or pain. The history will be obtained from the mother or nurse, and the onset of the disease is arrived at by questioning back day by day up to the time when the child was well. Disturbed sleep or irritability of temper has usually been noticed by the mother. If at all possible, the examination should be carried out while the child is asleep in his mother's arms, so that if he should awake he will not be alarmed. In the infant, therefore, it is best to complete the examination of the ears before that of the nose and throat. A view of the tympanic membranes is not difficult to obtain when an electric otoscope is used, and this instrument is to be recommended, especially for children. Gentle pressure on the chin is sufficient to cause wide opening of the mouth, thu allowing of a thorough examination of the mouth and fauces further, it is quite easy to inspect the anterior nares.

Frequently symptoms ascribed to the teething period ar found to be due to unrecognized inflammation in the middle ear cleft. The association of the eruption of teeth with middle ear disease is well recognized by many of the laity. Not lon ago an anxious mother brought her child for examinatio because his ears had not run when he was cutting his teeth

For reasons already explained, infants and children ar especially susceptible to the acute type of catarrhal otitis medi Any unexplained febrile illness in a child should lead to a care ful examination of the drumheads. Fever of 100° F. ofte sibility of finding a chemotherapeutic compound which will cure tuberculosis. At the present time the defeatist attitude which exists in the field of tuberculosis is to be deprecated, and it is a sad state of affairs that we are content to spend millions on palliative measures alone. What is needed is a drug to cure the disease, and the only answer is a scientific research unit planned on a nation-wide scale and backed by the country's resources. Untold millions have been spent on research for discoveries having any bearing on war, and yet a mere quarter of a million pounds is the Government's contribution to medical research each year. I can think of no better or more useful purpose than the application of science to finding a cure for tuberculosis. Furthermore, planned research to attack the problems of tuberculosis would be a fitting memorial to our Service men and women, many of whom are now lying in sanatoria throughout the country rendered *hors de combat* by the treacherous tubercle bacillus.

The political cry of the moment is for first things first. In medicine, too, there is a real need for such a maxim, and men of enterprise and ingenuity are needed to co-operate in an undertaking which would be whole-heartedly approved by all mankind.—I am, etc.,

Preston Hall, Maidstone. George R. W. N. Luntz.

Oedema during Macrocytic Anaemia

Sir,—The article by Lieut.-Col. E. G. Holmes (Oct. 27, p. 561) on the occurrence of oedema during the course of macrocytic anaemia raises some very interesting points which bear on the attitude towards the anaemias found in the Tropics.

(*a*) The description of the case DT./1574 includes the following data: 5/1/45, R.B.C. 1,830,000, Hb 38%, C.I. 1.05, etc.; 8/1/45, high protein diet; 21/1/45, reticulocytes 5%; 23/1/45, Hb 82%, R.B.C. 4,630,000. These figures represent an increase of R.B.C. 2,800,000 per c.mm. and Hb 44% in eighteen days. General experience would estimate the improvement in the case of pernicious anaemia of comparable severity, assuming the absence of any inhibiting factor such as sepsis or vitamin C deficiency and given adequate liver therapy with a preparation of proved efficiency, at about 800,000 R.B.C./c.mm. and an improvement of, say, 20% in the Hb. I do not question the accuracy of the observations made, but call attention to the disparity between the observed figures of improvement and those which might be expected. I believe that the explanation is probably to be found in the following suggestion. If a "hydraemia" existed on 5/1/45 which disappeared before 23/1/45 the blood count would show an "improvement" without the occurrence of a physiological reticulocytosis, and without any change at all in the rate of blood regeneration. Readers of the literature on the treatment of various types of anaemia found in the Tropics may note either a lack of reticulocyte response despite improvement, or a reticulocyte response much lower than would be expected with effective treatment of pernicious anaemia or a simple achlorhydric anaemia with the same initial count. I believe that part of the answer is that the true level is not expressed by the blood count, and that the reticulocytosis therefore corresponds to that expected in an effectively treated anaemia of less severity.

(*b*) The anaemia in these cases is described as "macrocytic" on the appearance of the cells in a blood film. The marrow, however, revealed a normoblastic response, and in the one case in which a report on the morphology of the cells is given no macroblasts or macrocytes are mentioned. (The author does state elsewhere: "Macrocytosis was observed in all cases"—p. 561, para. 4.) The colour index is raised, but even this is reversed in the later counts of the same case. One may reserve the opinion that the diagnosis is suspect in this case, but the form of the investigation forced on the author and his colleagues raises another point. On this I may be accused of splitting hairs, but I do believe it to be important because of the trap it lays for the unwary.

The term "macrocytosis" was coined for cells of large diameter, which incidentally have a larger volume. Since the technique of estimation of cell diameter is both tedious and time-consuming, the more easily estimated mean corpuscular volume is in general use, and the term "macrocytic" is applied to cells with a high corpuscular volume. In practice it is generally true that bloods showing a high M.C.V. are macrocytic, but they may be spherocytic. There is nothing fundamentally new in the comment that a macrocytic anaemia cannot be diagnosed on the haematocrit alone, but needs the confirmation provided by identifying macrocytes or macroblasts in the blood film. But if the anaemia shows little evidence of regeneration these cells may be hard to find. Those, therefore, who attempt short-cuts to diagnosis with these anaemias of the Tropics may find themselves treating on the basis of the M.C.V. cases which could not possibly respond to treatment for "macrocytic anaemia." Will the medical etymologists please produce a term other than "macrocyte" for the description of cells of large volume.

(*c*) Under the heading of treatment I would point out that liver, yeast, and yeast extracts are high-quality protein as well as being sources of substances specific in the treatment of truly macrocytic anaemias. Their value in treatment may depend on the former attribute rather than the latter, and their successful use in treatment is not a further argument for regarding the anaemia as "macrocytic" when laboratory facilities do not permit of exact diagnosis.

(*d*) This article, among others published recently, presages a new attitude in haematology which is fundamentally important—i.e., the change from haematology as "red-blood-corpusculology" to the study of the blood as a whole tissue. The subject can surely no longer remain the study of the particulate elements of the blood, but must also include the study of the matrix of those cells. My own rather sketchy attempts to work out some problems relating to anaemias in Assam suggest to me that many cases are brought about by protein deficiency resulting from poor diets plus the accidents of dysentery, pregnancy, etc., on top of which are the usually recognized deficiencies of iron, vitamin B complex, red cell maturation factors, etc.

Taking the article as a whole one is not impressed with the evidence for regarding these cases as macrocytic anaemias, but one must be appreciative of what is, I think, the first article describing a large group of cases in which a definite correlation is attempted between the state of hypoproteinaemia and disturbances of the A/G ratio and anaemia, and successful treatment is based on an argument which gives new significance to restoration of the blood proteins to normal levels.—I am, etc.,

Therapeutic Effect of Induced Jaundice

Sir,—Referring to the article by Drs. Frances Gardner, Alice Stewart, and F. O. MacCallum (Nov. 17, p. 677) on the therapeutic effect of induced jaundice in rheumatoid arthritis, some twelve years ago I noticed in a patient with leprosy, with lesions of the major tuberculoid type scattered all over the body, and who acquired severe jaundice, that all the lesions disappeared; also as the erythrocyte sedimentation rate was being tested every 7 or 14 days in the hospital where the patient was I noticed that the E.S.R. fell rapidly. The effect was so striking that I considered the question at the time of inducing jaundice as a therapeutic measure in leprosy, but was not successful in doing so.

About 18 months ago I had another case in which a woman had leprous lesions of a similar nature and who acquired an acute hepatic condition with severe jaundice. Within a few days all her lesions disappeared, and a few weeks later her hepatic condition cleared up temporarily and she seemed to be in excellent health. The latter condition, however, returned and ended fatally, but there was no return of the leprous lesions.

I think these records are worth considering, especially as mention is made in this article of a similar improvement in tuberculosis, a disease which so closely resembles leprosy in every respect.—I am, etc.,

Anticoagulant pH in E.S.R. Estimations

Sir,—It is known that neutral solutions of sodium citrate tend to become alkaline when sterilized by autoclaving. This effect varies with the glassware of the container, and increases with prolonged exposure to high temperatures, so that a final *p*H as high as 9.5 may be reached. For this reason special steps are usually taken to secure a more neutral solution for intravenous infusions and blood transfusion.

accompanies this acute catarrh, and when the condition is latent—that is, without pain or discharge—the patient may run such a temperature for some weeks. In one case, as a result of blocking of the Eustachian tube and the rarefaction of air in the middle ear, the tympanic membranes may be indrawn and the light reflex distorted or absent; while in another case, when as a result of hyperaemia an exudate takes place, the membrane will bulge outwards.

Pain is apparently spasmodic, and the mother will have noticed the child repeatedly putting a hand up to the affected ear. This is accompanied by fits of restlessness and crying. The further signs will depend upon such factors as whether the condition resolves either spontaneously or under treatment, or whether it remains as a catarrhal condition or goes on to suppuration with perforation of the membrane.

Before dealing with acute suppurative otitis media, I should like to mention tuberculous disease. This occurs most commonly in the first year of life, and is notable for the absence of pain. The first indication of its presence may be a watery curdy discharge from the ear or a painless swelling over the mastoid region; or it may be noticed that the "child cries with one side of his face only"—facial paralysis having resulted from the pressure of tuberculous granulation tissue on the exposed facial nerve in the middle ear.

In acute suppurative otitis media the temperature is higher—101 to 103° F.—and the general disturbance more intense than in acute catarrhal otitis media. The pain is more severe, so that the child may knock his head against the side of the cot. Occasionally meningismus, which quickly disappears after the tension in the middle ear has been relieved, is present. Pus in the meatus or on the pillow may direct attention to the ear if the disease has not been apparent in its early stages.

On examination with the otoscope the drumhead shows redness, and its insertion into the tympanic ring loses definition. It is impossible to distinguish the handle of the malleus, and the membrane begins to sag and redness of the deep meatal wall appears. If unrelieved by percentesis rupture of the membrane occurs, with discharge of the products of inflammation from the middle ear. In the child, on account of the relatively thicker drumhead, perforation may be longer delayed than in the adult, and instead of this occurring in two or three days it may take eight or ten.

There appears to be a quality in some strains of infection which causes the middle-ear cleft to be attacked. We are all familiar with epidemics in which there is a high incidence of aural infection, and also with other epidemics, not less severe, in which the complications are pulmonary or gastro-intestinal. For that reason it is important to recognize early if otitis media is complicating a specific epidemic, in order that treatment may at once be carried out. This was well seen in a recent epidemic of gastro-enteritis in infants when a large proportion of the patients had aural complications.

Treatment

It is questionable if any developments in surgery have done more for the general health and well-being of the community than the enormous progress made in the treatment of the nose, mouth, and throat. The reduction in cases of chronic otorrhoea as well as of enlarged cervical glands, of adenoid facies, of stunted chests, and of undeveloped adolescents is evident since the operation for removal of adenoids and tonsils came into vogue. It is a most depressing daily occurrence in dispensary practice to be asked for advice on behalf of a child with ear inflammation by an anxious guardian, herself the seat of obvious chronic rhinitis and dental sepsis. The treatment of these conditions or of chronic suppurative otitis media in the parent may be a not unimportant step in the treatment of the child.

Attention has been drawn already to the need for a careful general preliminary examination in daylight, and a urine test at this stage may be of considerable value. Not infrequently anaemia or constipation, bronchitis, enteritis, or, in female children, pyelitis may require treatment at the same time. If the fever has been long sustained a marked resistance to the infection may be obtained if the urine be rendered alkaline by means of copious alkaline drinks.

A word of warning must be given about indiscriminate sulphonamide therapy. "Sulpha" drugs should not be used in ear disease unless combined with surgical treatment. Naturally, situations may arise where this is not possible, and, in the absence of contraindications, these drugs are best given in maximum doses until the patient has been brought to the otologist. For the preservation of the hearing, and on occasions of life itself, all patients who are receiving sulphonamides for ear disease ought to be examined by an otologist as early as possible in the course of the treatment. That we are most grateful for these life-saving drugs goes without saying, but it is necessary to show some discrimination in the cases chosen for their use.

In local treatment it is to be emphasized that freeing of the nasal airway is of first importance when once ear disease has established itself. It is equally to be remembered that until this unfortunate complication of otitis media is established little interference with the anterior nares is permissible. If the temperature is very high early in an illness in which symptoms and signs are referable only to the middle ears, look to the nasopharynx, from which large inflamed surface much of the toxaemia may be arising. Freeing of the anterior nasal obstruction by means of steam inhalations of friars' balsam and menthol, followed immediately by pouring into the nostrils, with the neck extended, a teaspoonful of parolein, will bring about a quick change in lessened absorption of toxins from the nasopharynx and pharynx. Not only acute but subacute otitis media may resolve more readily in the presence of adequate ventilation and drainage of the nose and nasopharynx. In catarrhal otitis media these simple measures, combined with the instillation of warm ear-drops of 1% carbolic in glycerin, may suffice, so long as the effusion is serous and of short duration.

Occasionally, however, the serous condition does not improve. Here treatment is particularly important from the fact that the disease, if unchecked in its early stages, represents the starting-point of morbid processes leading to deafness later on in life. The proper treatment is paracentesis with a fine myringotome, followed by a course of Eustachian-tube inflation. Uncalled-for sulphonamide medication may mask the symptoms and prevent adequate treatment. It is my opinion that these simple measures of paracentesis of the drumheads, followed by inflation of the Eustachian-tubes, are not resorted to often enough. I feel that cases of deafness labelled later on in life as dry catarrh or otosclerosis would be less frequent if these harmless operations were more common in childhood. No one may be blamed for the omission of earlier treatment: Nature endows the patient normally with such reserves of hearing that much damage has already occurred before he complains. Indeed, a child may lose one-third or more of his hearing power before any disability is noticed. The appearance of pure-tone audiometers marks an advance in diagnosis, and their use in schools is likely to direct our attention to those cases of latent catarrhal otitis media, so that paracentesis and Politzer inflation may be instituted earlier. Even in adults, and certainly in children, it is not possible to arrive at a quantitative evaluation of hearing loss except by audiometric measurement. It seems, therefore, that such accurate early diagnosis, followed by paracentesis of the drum and expression of plugs of mucus from the middle-ear clefts by inflation, may in the future contribute to the reduction of deafness.

Patent nasal, post-nasal, and Eustachian-tube passages, it has been seen, are necessary for successful treatment of ear inflammation, and, while major operative treatment in the anterior nares is seldom required in children, it should be remembered that recurrence of adenoids after the age of 10 is occasionally due to nasal sepsis—for example, antrum infection. Removal of such a recurring mass of adenoids is essential, and should be done during a quiescent period, but care must be taken to avoid injury to the cartilages of the Eustachian tubes. Some weeks after operation for adenoids a course of inflation of the middle ears may be necessary to prevent adhesive changes taking place.

A word may be said about paracentesis. Before carrying out this operation the meatus must be made surgically clean by mopping out with an antiseptic. Acriflavine 1/2000 of spirit has been found useful in the past, but a small experience with penicillin suggests that here, as in other directions, this drug will prove of the greatest value. Prevention of injury to the skin of the meatus and middle-ear structures by the discharges, and promotion of healing while preventing secondary

The following experiment was carried out to discover the effect of such variations in *p*H upon E.S.R. determinations by the Westergren method. Three bottles of 3.8% sodium citrate solution were autoclaved at 15 lb. pressure for increasing lengths of time. The *p*H levels then determined were 7.8, 8.5, and 9.5 in the different bottles. An acidified solution of *p*H 6.5 was also prepared. Four simultaneous E.S.R. measurements were then made on the blood of three patients, using a different citrate solution for each of the four measurements. At the end of one hour readings were taken. In one patient the levels were equal in all four tubes, but in the other two the readings were greater in the tubes containing alkaline citrate, the greatest difference being 2.5 mm. between 10 mm. and 12.5 mm. (a 25% addition).

It appears, therefore, that the *p*H of the anticoagulant can affect the E.S.R. reading; and that for comparable results to be obtained a standard anticoagulant of specified *p*H should be used.—I am, etc.,

Bridge of Earn Hospital, Perthshire. M. E. MORGAN THOMAS.

Transmission of Hepatitis during Blood Transfusion

SIR,—It is an established fact that hepatitis (homologous serum jaundice) can occur two to six months after transfusion of human serum or plasma. In some episodes it has been possible to incriminate certain batches. With some batches the incidence of affected persons has been as high as 60%. In other instances only isolated cases occurred, and the vast majority of recipients showed no ill effects. In the first group the transmission of an icterogenic agent is undoubted. The cases in the second group are more difficult to understand. An explanation might be that apart from the serum or plasma used some icterogenic material was administered accidentally. Such an inoculation will occur through syringes contaminated with icterogenic material and inadequately sterilized between injections (*Lancet*, 1945, 2, 116). Moreover, in some hospitals a Higginson syringe is used for creating a positive pressure in the transfusion bottle. This Higginson syringe is not always sterilized before use, but is attached to the bottle by a sterile glass tube containing the cotton-wool plug acting as a filter. If one such transfusion were carried out with icterogenic material, the Higginson syringe may, by reflux of the icterogenic material, be contaminated and later on the icterogenic agent passed on to bland bottles. The cotton-wool plug in the connecting glass tube may not afford enough protection. It should be, therefore, a routine to clean and autoclave Higginson syringes after each transfusion in order to avoid the possible transmission of hepatitis by this method.—I am, etc.,

S W London Blood Supply Depot, Sutton. K. MAUNSELL.

Artificial Pneumothorax Needle

SIR,—Dr. A. Allan's article (Nov. 3, p. 607) describing a needle specially designed to minimize the grave danger of air embolism in artificial pneumothorax work prompts me to mention a simple technique which I adopted for similar reasons.

Any refill needle is used that will fit on a Record syringe; I find a 1-c.cm. syringe a convenient size. So fitted, the needle is inserted through the chest wall into the pneumothorax space. The piston of the syringe is then withdrawn, and if the needle is correctly inserted air must enter the syringe and thus give absolute proof that the aperture of the needle is not in soft tissue. At the same time the needle is cleared of any remaining drop of fluid. Then by a feat of dexterity (easily achieved by five minutes' practice beforehand) the syringe is detached while the needle is left *in situ*, and the rubber tubing from the refill apparatus is connected in its place. I use a small metal connecting-piece on the end of the rubber tubing, so that the nozzle of the rubber tubing is made exactly similar to that of the Record syringe. The change-over should easily be made in less than a second, and if carried out during expiration no unfiltered air enters the chest, and the amount of air blown out is so small as not to affect the pressure readings. If a Maxwell's refill apparatus is used and the air is run in not too fast the manometer registers a swing throughout the refill, thus enhancing the certainty that all is well. I would emphasize Dr. Allan's statement that one has to experience the feeling of confidence which results to appreciate the value of certainty that the needle is correctly inserted. During the refill, should the operator suspect that the needle may have slipped, it is easy to reverse the change of nozzle and repeat the attempt to withdraw air. In addition to reassurance this commonly clears the needle of a little blood.

This technique confirms the presence of an air space before any air is run in should, by any chance, the patient not have been screened immediately prior to refill. It also avoids using a wide-bore needle, with the attendant anaesthetic. I disagree with Dr. Allan that "humanity and common sense call for the anaesthetization of the needle-track." Provided that the needle is inserted swiftly, and withdrawn swiftly—which is important—practically every patient I have come across prefers to be refilled without anaesthesia. I certainly do myself.—I am, etc.,

Tuberculosis Dispensary, Reading. W. H. TATTERSALL.

Acute Inversion of the Uterus

SIR,—On reading Dr. Doreen Daley's letter on acute inversion of the uterus (Nov. 3, p. 626) one or two questions arise naturally in one's mind. For instance, the writer implies, though not distinctly stating, some surprise "that such strenuous efforts to combat the shock were quite ineffective *until replacement was carried out.*" Apart from the well-known difficulty of getting anything into the circulation at all when the blood pressure is reduced so low as is usual in cases of shock, one would have thought that the maxim that the first step in the treatment of any disease is to remove, if possible, the cause rather than to treat the symptoms would apply equally well to the treatment of acute inversion of the uterus. So long as the chief cause of shock persists it is hardly reasonable to expect the shock to respond to other treatment. One can have little doubt that, as the writer says, this woman would have died but for the correction of the inversion of the uterus.

Then there arises a further question. In a case where there has been severe haemorrhage a blood transfusion is obviously indicated. But why proceed to put 10 pints of blood into the circulatory system of a patient who was believed to have lost some 4 pints, not to mention the following up of this big transfusion by "a slow saline drip continued for a few more hours"? There must surely be a limit to the capacity of the circulatory system. It is generally stated in textbooks on physiology that the average amount of blood in the body is round about 12 to 13 pints, and recognized authorities on blood transfusion have stressed the dangers of giving excessive amounts. Besides blood transfusion the patient was given methedrine—twice—as well as ergometrine; and subsequently it was thought proper, *for prophylactic purposes only*, to give sulphadiazine and *B. welchii* serum.

Now, I ask, how is it possible to adjudge the effects of so many different remedies given within one short period of time? This patient in grave danger needed: (1) a supply of fresh blood to make up for the loss; (2) replacement of the uterus, the inversion of which was the main cause of all the trouble; whether the one or the other should take first place we leave to the experts. How far the other injections were worth anything, or even justifiable before the replacement of the uterus, is open to doubt, and I should really be glad to know on what grounds scientifically the transfusion of as much as 10 pints of blood plus a 4-hours saline drip infusion is justified.

It is true that it would be very easy to quote any number of articles or letters in the medical journals of recent years in which at least half a dozen different drugs, all requiring great caution in usage, had been administered within the space of a few hours for various emergencies (or even in the mere "premedication" preliminary to anaesthesia). The patient, of course, makes a wonderful recovery, but we are left wondering how far all the medication assisted, or whether the patient is not to be rather congratulated on having successfully survived the bombardment. But I have chosen this particular case, in which the medication is relatively quite mild, because of the special interest attaching to the blood transfusion, and because I feel sure that there is much abuse of this most useful measure.

I make no pretence to any special knowledge of obstetrics, but write only from a general medical standpoint and, as one belonging to the now vanishing Victorian-Edwardian-Georgian era, I shall be only too pleased if the adherents of the modern school of therapeutics can convince me that my doubts as to the great advances in the scientific use of new drugs (in the wide infection from entering from the meatus, are of paramount importance and call for the use of a unique antiseptic. The incision in the tympanic membrane is done under a general anaesthetic and with good illumination of the drumhead. It is made from below upwards in the most bulging portion of the posterior half of the drum, and may extend beyond the pars tensa of the drum into Shrapnell's membrane. A wick of sterile gauze, which is kept moist with the antiseptic of choice, is placed in contact with the incision in the drum to serve as a drain.

Chronic Suppurative Otitis Media.—No consideration of ear disease in children would be complete without reference to this condition, which is still too frequent among our school-children. Not uncommonly it is already of some years' standing when the child arrives at the age for attending school. The parents may not have sought advice for what in their opinion was a trifling complaint, and as a result of repeated infection from the external auditory meatus the disease, even at this early age, may be deep-seated and associated with osteitis in the "honeycomb" of the mastoid air cells. It is worthy of repetition that, in these untreated cases, if it were not for the secondary infection from the outer ear, middle-ear inflammation would lose half its significance. In the course of numerous operations done for chronic suppuration in children it has been my experience that the destruction of the bone of the mastoid and the delicate middle-ear structures is usually greater at operation than had appeared to be likely. It is frequently our custom to persist for years in various kinds of conservative treatment, in the hope that these, added to increased general resistance to disease acquired with the years, may tip the balance in favour of resolution of the chronic inflammation. I am of the opinion that no benefit to the patient's hearing is likely to follow from delaying operation after five years of conservative treatment has been tried without cessation of the discharges. Healing may occur after some further years of treatment, it is true, but these years of ulceration in the middle ear and mastoid cells will have taken their toll of the delicate hearing mechanism. With the healing an increased amount of scar tissue is laid down; fixation of parts which should move is more prominent, and increased deafness is the result. Prolonged toxaemia from the chronically inflamed bone may have permanently affected the sensitive end-organ in the labyrinth, and may have laid the foundation for an even more resistant deafness. An operation performed on those patients before leaving school would save much time spent in dispensaries in later years; and, what is more important, would reduce considerably the incidence of deafness among our adult population. If a modified radical mastoid operation (modified to preserve the middle-ear structures and the hearing) is followed by the same careful conservative treatment which these children get before operation, a better-hearing ear is usually the result in a few weeks. Improvement in hearing must not be sacrificed for early cessation of discharge. The latter takes place usually within a matter of months. The mental brightening and physical benefits in school-children which so often follow a modified radical mastoid operation for chronic suppurative otitis media make the operation one of the most satisfactory to both patient and surgeon.

The Lasker Award in Mental Hygiene, which was instituted in 1944, has this year been presented jointly to Major-Gen. G. Brock Chisholm (now Deputy Minister of Health for Canada) and to Dr. J. R. Rees, medical director of the Tavistock Clinic, London, and lately consulting psychiatrist to the Army with the rank of brigadier. This award, given for outstanding contributions to the advancement of mental health, has special reference in the current year to rehabilitation. It was presented on Nov. 1 in New York at the annual meeting of the National Committee for Mental Hygiene by General Omar C. Bradley, who is now in charge of the Veterans Administration of the United States. The citation for Dr. Rees, read by Gen. Bradley, was written by Prof. John C. Whitehorn, of Johns Hopkins University. It paid warm tribute to his leadership and encouragement in bringing together a remarkable group of psychiatrists to apply the best available scientific knowledge of human nature to aid the Army in the use of its man-power. "In particular, Brig. Rees and his associates developed the preventive aspect of Army psychiatry. Eminently practical contributions thereto were made through the systematic use of psychological and psychiatric skills in the selection of officers for qualities of leadership and through the application of psychiatric principles in the assignment of men to special duties."

POISONING DUE TO MOBILIZATION OF LEAD FROM THE SKELETON BY LEUKAEMIC HYPERPLASIA OF BONE MARROW

BY

ALEXANDER BROWN, M.D.Glas., M.R.C.P.Ed.

AND

SIDNEY LIONEL TOMPSETT, D.Sc.Glas., Ph.D.Glas., B.Sc.Lond., F.R.I.C.

(*From the Royal Infirmary, Glasgow*)

It is now generally recognized that traces of lead are present in all the tissues of the body even in normal subjects. Relatively large amounts occur in the bones, and the more recently absorbed lead is deposited in the trabeculae—a situation from which it may be readily mobilized. Under conditions of increased exposure and increased storage, mobilization may produce lead-poisoning. In the following case mobilization occurred in an unusual manner owing to leukaemic marrow hyperplasia.

Case Record

Wm. M., aged 31, had been a compositor for 12 years, and until Sept., 1939, had enjoyed perfect health. At this time, over a period of about two days, he became seriously ill. He had severe occipital headache and pain and stiffness in the posterior cervical muscles. Both became progressively more severe, and within the next two weeks gradual paralysis of the muscles of mastication developed. Left facial and right hypoglossal paralysis followed. Diplopia, blurred vision, and vomiting appeared during the next few days. Within 10 weeks of the onset of the illness there were complete facial paralysis, almost complete paralysis of the muscles of mastication, and general weakness of all the skeletal muscles to such a degree as to confine him to bed. Intractable pain had developed in the shoulders and arms, thirst was excessive, and constipation very marked.

On admission to hospital on Dec. 1, 1939, he had obviously lost a great deal of weight. He was drowsy, cerebration and speech were very slow, and general muscular weakness was so marked that he was almost completely helpless. Mastication was impossible, and even swallowing was difficult. All tendon reflexes were greatly diminished. The B.P. was 110/90. No obvious cardiovascular disease was present. The mouth, gums, and teeth were healthy. The fundi were normal. The cerebrospinal fluid was normal except for a slight increase in lymphocytes. The blood urea was 25 mg. per 100 c.cm. During the week following admission there was mild pyrexia (100° F.). Vomiting occurred on several occasions. Headache and confusion were almost constant. On Dec. 20, 1939, when both red cell and white cell counts were normal, the blood lead was 280 microgrammes per 100 c.cm. On Dec. 31, for the first time, examination of the fundi revealed signs indicating early papilloedema. His blood picture was then still normal (Table I), but the blood lead had risen to 455 microgrammes per 100 c.cm. Throughout January and the greater part of February, 1940, the patient's general condition deteriorated slowly. At the beginning of March it was evident that a leukaemic state was developing, and its progress and morpho-

sense) and of blood transfusion on the heroic scale, claimed by them, are groundless. For the present I fall back on ancient authorities such as our old friend, Sir William Osler (" an enemy of indiscriminate drugging," to use his own words), or that old stickler for the accurate investigation of new methods of treatment, Sir James Mackenzie; and would hold up as worthy of the notice of the modern school of " go-aheads " that old motto, *Primum non nocere*.—I am, etc.,

Southborough, Tunbridge Wells. E. WEATHERHEAD.

Ergometrine in Migraine

SIR,—In the *Journal* of Nov. 10 (p. 654) appears an annotation in which you discusss the use of certain alkaloids of ergot in the treatment of migraine. Surprisingly no mention is made of ergometrine, which has proved its value. Yet it was in the *Journal* some five years ago (Dec. 14, 1940, p. 849) that Dr. A. G. Auld of Harley Street wrote to commend it. Since that time I myself have used it both orally and by injection with great satisfaction. The dose is 1.0 mg. by mouth or 0.5 mg. by injection. Injection is only necessary when there is vomiting or nausea. Patients are convinced of its efficacy, as their attacks are either prevented or promptly curtailed.

This letter is written in the hope that the information may be of service to other practitioners who missed Dr. Auld's original notice.—I am, etc.,

Sedbergh. H. THISTLETHWAITE.

The Discharging Lesion

SIR,—No one doubts the storing up of energy in the form of intracellular substances which is available for function, and energy may be released as physiological stimuli under abnormal conditions. In the supposed case of release of energy not as growth or physiological stimuli the result is merely destruction of the cell involved. Hyperexcitability should not be applied to instability of cell constituents, since it is a property of the intact cell.

Your report of the meeting of the Section of Neurology of the Royal Society of Medicine (Oct. 27, p. 580) quotes Dr. J. Purdon Martin as saying: " Energy might be discharged without a physiological stimulus " ; and " there might be a state of instability of the energy substance, and this might be the basis, etc." Would he define more clearly his own views upon this, " energy substance," the " imperfectly recovered cell," and the mechanism of " excessive response to normal stimuli " ?

Nerve cells degenerate when exhausted and insufficiently supplied with material for recovery. In sleep, anaesthesia, and hibernation all exhaustion is prevented, and moderate reduction in blood supply is not then harmful; but in sick or elderly people exhaustion of the nerve elements by severe stimuli or other forms of shock results in lasting clinical effects because their normal or reduced local cerebral blood supply is insufficient to allow of complete recovery.

Alexander and Woodhall (*J. Neuropath. exper. Neurol.*, 1943, **2**, 1) showed that the presence of nerve cells with normally functioning axonal and dendritic processes within an area of brain tissue degeneration constituted the truly epileptogenous lesion. Where the locus of such epileptogenous foci can be determined then the cutting of the axones is beneficial, provided the necessary cutting of near-by normal tissue does not introduce more serious disadvantages. This principle is also used for treatment of intractable neuralgias and for mental disease.

Faulty integration of cell impulses is the cause of untoward clinical symptoms. This is not attributable to any instability of cell constituents, but to a lowering or heightening of the threshold of stimulation of neurone groups by pathological alteration of the pattern of blood flow which predetermines the faulty reflex pathways.—I am, etc.,

Medical School,
Hospital Centre, Birmingham. F. A. PICKWORTH.

Surgical Catgut

SIR,—Mr. J. Hosford, in his letter (Nov. 10, p. 668) regarding the variation in strength of sterilized catgut ligatures prepared by British manufacturers, overlooked the difficult conditions under which the various firms worked during the war to meet the demands of surgeons and hospitals in this country, also supplies for the Services and export trade. In 1944 minimum standards of strength and gauge were included in a Supplement to the *British Pharmaceutical Codex*, 1934, to which all manufacturers of sterilized catgut ligatures conform, thereby eliminating so far as possible variation in gauge and tensile strength. I have used sterilized catgut of British manufacture throughout the war and have found it as good as that produced by any American firm.—I am, etc.,

London, W.1. CECIL P. G. WAKELEY.

SIR,—I would like to support very strongly the letter of Mr. John Hosford. Most of us have had trouble with catgut since the war. I believe that at present most of the chromicizing is unreliable, the rate of absorption varies tremendously as well as the tension and size and, I regret to say, sterility. I believe that the raw material for making catgut in this country is all imported, and from the point of view of shipping space the manufactured article would probably take up less room. I realize that the dollar position makes things difficult, but surely this is a matter which can be overcome. Material of less vital importance is imported—for example, £20,000,000 is spent annually on American films—and where the welfare and even the life of our patients are at stake we should be able to use catgut upon which we can rely.—I am, etc.,

Hove. H. J. McCURRICH.

Acute Yellow Atrophy after Trilene Anaesthesia

SIR,—After reading the interesting case report by Major K. N. Herdman (Nov. 17, p. 689) it occurs to me that perhaps trichlorethylene was not the primary cause of the liver necrosis in this case, although it may have been a contributing factor. Despite the current practice in many clinics some anaesthetists still consider 0.8 g. (16 c.cm.) of pentothal an excessive dose for induction of anaesthesia, especially when preceded by 1/4 gr. morphine. In this particular case there is the added complication that the liver may already have been damaged by previous sepsis.

According to Adriani (*The Pharmacology of Anaesthetic Drugs*, 1942) the liver function is decreased by both barbiturates and morphine, the glycogen being depleted and the blood sugar raised. In the case of pentothal and other short-acting barbiturates special caution is necessary, as these drugs are almost entirely detoxicated in the liver. Langton Hewer (*Recent Advances in Anaesthesia*, p. 129) writes: " Pentothal sodium, unlike evipan sodium, is extremely toxic to the liver in small animals such as mice, and it is worth noting that toxic jaundice has occurred in man."

I would like to congratulate Major Herdman on his excellent report, which should stimulate considerable interest and discussion.—I am, etc.,

Newcastle-upon-Tyne. PHILIP AYRE.

SIR,—In his report of a case of acute yellow atrophy of the liver following trilene anaesthesia (Nov. 17, p. 689) Major Herdman has not considered another possible aetiological factor. The interval between the injury and symptoms of hepatitis was 93 days, which is about the usual incubation period of homologous serum jaundice. As the patient was treated for burns in two B.L.A. hospitals plasma or serum may have been administered, and this factor should be excluded before incriminating the anaesthetic.—I am, etc.,

London Hospital, E.1. CLIFFORD WILSON.

Sciatic Neuritis

SIR,—Dr. J. MacD. Holmes and Mr. B. R. Sworn in their paper with this title (*Journal*, 1945, **2**, 350) describe swelling and oedema of the first sciatic nerve root in two cases of sciatic pain and of adhesions around the root in a third. In their comment they write: " We must for the moment be content with having seen a lesion which Symonds considers has not yet been granted to human eyes."

The swollen condition of the nerve root commented on by the writers is one with which most neurosurgeons are familiar, and I have frequently demonstrated it at operation as evidence of the radiculitis which is the common cause of sciatica. The lesion referred to by Dr. C. P. Symonds, however, was regarded as affecting the sciatic nerve itself. Except in a case of direct injury of the nerve trunk by a piece of glass I have never seen it, and in common with Dr. Symonds and others believe it to be but a figment of the imagination of earlier writers on sciatica. Swelling of the nerve roots (radiculitis) composing it must be clearly distinguished from swelling of the sciatic nerve trunk itself (neuritis).

I have just received my copy of the *Journal* for Sept. 15, and by the time this letter reaches you others may have already passed similar comment on the distinction which the writers of the paper have apparently overlooked.—I am, etc.,

Sydney, N.S.W. LAMBERT ROGERS.

Pellagra in a Morphine Addict

SIR,—With regard to Major Ellis Stungo's comments (Oct. 20, p. 547) on the case report by Dr. Comerford and myself, I note that he suggests that the patient "remained a morphine addict" throughout the period of treatment. I am not quite clear as to what is meant by this, but I can state categorically that the patient received no sedatives after her first day in hospital. Further, I am inclined to believe her statement that she ceased taking morphine after her discharge from hospital: first, because her original source of supply was then no longer available, and, secondly, because of the confirmatory evidence of her son. I am sorry if in improving rapidly despite an abrupt withdrawal of the drug of addiction our patient offended against Major Stungo's sense of the clinical proprieties, but the logic of events is the strongest logic of all.—I am, etc.,

St. Mary Cray, Kent. BRIAN H. KIRMAN.

Clinical Photography

SIR,—The *British Medical Journal* as the practitioner's weekly technical instructor appears to lag in its seeming omission of the pictorial method of conveying clinical information by photographic illustration, the occasional pictures reproduced being few, too small, and not of the first order.

As a visual aid to memory, next best to contemplating the patient in person, particularly helpful to the busy practitioner, pictorial reproductions would make a valuable improvement. This might be effected in one of three ways: (1) by interpolating from time to time in the *Journal* a sheet of fully captioned clinical pictures printed back and front, as suitable material became available; (2) by the occasional issue of a photographic supplement to the *Journal*; (3) by the publishing of a British medical photographic journal, quarterly or bi-yearly, additional to the number of subsidiary journals produced by the Association, taking precedence in time to others. Such an addition to our medical literature would prove itself to be a great attraction to the medical man—greater by far than any of these "specialist" journals.

A medical photographer co-opted by the Journal Committee would advise in choice of illustrations from the likely ample supply in the hands of the many widely scattered medical photographers, who would doubtless explore all fields, including that buried in past medical writings, now copyright-free, whence numbers deserve to be exhumed to live again even for a day. Photographic reproductions of both the usual and the unusual would relieve the tedious monotony of the printed page. Change being the spirit of the age, this would assuredly be one welcomed by members, not to be for any trifling excuse longer postponed.

The subject of clinical photography is important by reason of its growing magnitude, presently unrealized: its educative value cannot be gainsaid; than this, nothing could be more useful as a ready aid to diagnostic memory, and in cultivating the photogenic mind. In the *Journal* the display of the pictorial need not be sectional only, but should find room in the body of the paper to relieve original articles.

All medical men in practice appreciate the high value of the *B.M.J.*, upon which they continue to depend for practical instruction, and the renewal of the varied interests which it brings without fail from week to week. Our debt to the *Journal*, illustrated as suggested it ought to be, would be greater than ever. Such illustrating might encourage the initiation in medical schools of the clinical picture 'gallery', and of the lantern lecture, as a means of instructing medical students and graduates—one hitherto passed by and sadly neglected. It is of pleasing interest to know that Dr. C. O. Hawthorne, for so long a pillar of strength to the British Medical Association, was a pioneer in this country of the pictorial art in teaching. His example would do well to be followed wherever students are taught.—I am, etc.,

Bournemouth. S. WATSON SMITH.

*** Dr. Watson Smith may recall that before September, 1939, we used to include four-page photogravure insets at intervals of approximately five weeks. Paper has been very scarce for six years and still is.—ED., *B.M.J.*

Medical Aspects of Prisons

SIR,—After a careful study of the recent correspondence on this topic I cannot but deplore the emotional sentimentalism which induces some people to rush into print to champion the unscrupulous, and, in too many cases, the amoral and professional law-breaker who preys upon society. Before we bewail the sufferings of the criminal due to the lack of *ideal* sanitation in prison, might we not spare a thought for the overcrowded occupants of the thousands of back-to-back houses, where the few lavatories for the whole street are situated at the ends of the street? Think of the sanitary conditions of our slums. Are these law-abiding but unfortunate citizens—mothers, expectant mothers, and young children—to live in squalor and misery while we rebuild all our prisons with a water-closet to each prisoner? When we think of the poor criminal eating his carefully balanced and well-cooked diet, which throughout the war has contained his full quota of rations and more meat and vegetables than the average worker could obtain (due to purchases in bulk), spare a thought for the children of the poor who have been brought up on bread, margarine, cheap jam, and tea, with chipped potatoes as an occasional delicacy, since the days of the industrial revolution.

Most of this rather misdirected sympathy derives from the doctrine that crime *per se* is an illness: that you simply cure the patient (the criminal) and he commits crime no more. Naivety personified. Why have we not cured rheumatism, the common cold and cancer? Why are our mental hospitals congested with patients our psychiatrists cannot cure, and grossly understaffed? We are to apply in our prisons "the great advances which have been made in recent years by psychiatry in the understanding treatment and prevention of antisocial behaviour." What are these advances of, say, the last ten years, especially in the treatment and prevention of antisocial behaviour? What experience in their application has Dr. Ahrenfeldt and what are his results? On what grounds does he say that "the authorities still remain far behind contemporary psychiatric, educational, and sociological research in the field of criminology"? If there is one group of cases which is the despair of the practising psychiatrist it is the group known as the constitutional psychopaths, and, after the group of professional criminals who are normal psychiatrically if not morally, and who hold the belief that they can make crime pay, the psychopathic group is also a problem to the prison authorities.

Unfortunately for its reputation Civil Service medicine does not publicize, but that is no ground for assuming that it is inactive or non-progressive. Actually there is no recent development in modern psychiatry which has not been utilized in prison medicine, or for which facilities for its use have not been authorized where it would be considered justifiable or worth while—e.g, electro-encephalography or electro-convulsive therapy.

If some of these armchair critics would rally to the help of the prison and civil authorities by joining as *active workers* one of the organizations such as the Discharged Prisoners Aid Society or the Central Association for the Aid of Discharged Convicts, which seek to give a helping hand to ex-prisoners trying in the face of extreme difficulty to rehabilitate themselves socially, they would learn the real nature of some of the grievous problems with which the prison authorities, with their extreme shortage of staff and lack of suitable buildings, not to mention an unaccountably swollen prison population, have to grapple. The world to-day needs workers, not talkers.—I am, etc.,

"REALIST."

The "Stamping" of the Guards

Sir,—No man could complain of Major E. Grey Turner's courtesy (Nov. 17, p. 707) in his attempt to correct my perspective and want of understanding. Is it the correct perspective of a medical officer to apportion the price paid by the bodily injuries of a soldier in the cause of so-called smartness? It seems to me that his duties lie in a more humane and medical direction. If the drill is considered by authority essential to smartness then it seems to me also essential for the medical officer to point out the existence of the positive dangers involved and do his best to stop them.

My understanding of this problem and the charge of ineptitude of some medical officers were founded on the confessions of a retired senior officer of the Guards Brigade who did not sign his name to a letter he wrote in this particular correspondence in the *British Medical Journal.*—I am, etc.,

Stanmore. G. Lenthal Cheatle.

Sir,—I have been following with interest the correspondence from Sir Lenthal Cheatle and two R.M.O.s of the Brigade of Guards. It is depressing to think that neither an R.M.O. nor an A.D.M.S. has the power or the courage to put a stop to a form of ceremonial drill which admittedly jeopardizes the men's health. One wonders what exactly is the function of an R.M.O. I consider that the letter written by Major E. Grey Turner is an indictment against himself. He is prepared to allow "some varicose veins and a few cases of march fracture" to occur in his battalion in order to enhance Britain's propaganda abroad when the Coldstream Guards stamp their feet on parade!

It seems a pity that any R.M.O. should be so weak as to allow a form of drill which produces a fracture to continue without a word of protest or even advice from a "doctor in uniform."—I am, etc.,

Edinburgh. J. W. Perrott.

Volvulus of Small Intestine

Sir,—Major Salisbury Woods reports a case of volvulus of the small intestine. May I as a junior member of the profession add a case, which I personally operated on, to the list of this comparatively rare condition?

It was my week-end on "emergencies" and I was called to see a woman of 35 years who, believe it or not, had walked into the casualty department at 4.30 a.m. on Saturday morning. I came along to the casualty department to see her. The first thing that greeted me was a bilious vomit over my dressing-gown. She was vomiting copiously, complained of severe colicky abdominal pain, was obviously shocked and on the verge of collapse. It was next to impossible to obtain a history from her because she insisted on saying, "I'm all right, doctor; I must go home as my husband is due back on leave." Each time I endeavoured to get a history she again said, "I'll be all right now, doctor." I looked at her abdomen and noticed: (1) a Kocher's incision; (2) a lower right paramedian incision; (3) a left paramedian incision; (4) obvious distension. On examination I was certain of palpating some sort of a lump below the umbilicus in midline. On further questioning I gathered that she had passed neither faeces nor flatus per rectum for about thirty-six hours.

After much persuasion she consented to come in. I tried hard to persuade her to allow me to operate but she refused, all on the grounds that she would have to be home when her husband arrived. Because of the incessant vomiting, distension, and absolute constipation I had suspected intestinal obstruction due to a band or adhesion, but still she refused operation. I put her up on a glucose-saline intravenous drip, passed a Ryle tube, and ordered after two enemas a high rectal tube. Ultimately under much pressure and persuasion, together with my Irish blarney, she consented to operation at 6 p.m. in the evening.

I took her to the theatre. Under a general anaesthetic, given by the house-physician, Dr. D. McGrath, I made my incision medial to the left paramedian scar. On opening the peritoneum I found blood-stained fluid. With the aid of the "sucker" I removed about 1½ pints of this blood-stained fluid. I then saw coils of dark, black, distended bowel. On further examination I identified a volvulus of the small intestine due to a very thick band travelling from the site of the right paramedian scar to the root of the mesentery. The small intestine had rotated three times around this band. I divided the adhesion immediately and undid the volvulus. Despite hot bathing with saline to the black bowel there was no return to peristalsis or sheen. I therefore presumed the affected part to be dead. I then resected nearly 3 feet of the affected bowel and did an end-to-end anastomosis and closed the abdomen with drainage. When we got the patient back to the ward I put her up on plasma. She had 2 pints of plasma and 3 pints of glucose-saline. Thirty-six hours after operation I put her on full doses of sulphasuxidine. She waxed and waned for about nine days and then began to "come out of the wood." She was discharged from hospital five weeks later and felt perfectly well. My thanks are due to Mr. C. M. Pearce, F.R.C.S., for granting me permission to publish this case.—I am, etc.,

Blackpool. Stanley Devlin.

Welfare Work a Branch of Medicine

Sir,—In your issue of March 17 (p. 357) in an article by Lord Horder on "Shall we Nationalize Medicine?" he asks: "Is welfare work really a branch of medicine?" Is there really any doubt as to the answer to this question? "Doctor" means "teacher"; it does not mean a bottle of medicine. Surely the basic function of the doctor is to teach his patient to be healthy, whether that teaching implies medication, operation, how to avoid them, or merely by blowing off steam.

Lord Horder goes on to quote an admirable passage from Nathaniel Hawthorne describing the ideal doctor–patient relation: "He deemed it essential, it would seem, to know the man before attempting to do him good." This is the very quintessence of welfare work: to know the man in whatever size, shape, colour, or age he may be presented, and to try to do him good. If welfare work has failed in this it is because our schools of medicine have been separated from it and take up a detached and critical attitude towards it. I hold absolutely no brief for work that is stereotyped and formulated, but it is only by being an integral part of medicine that sanity in welfare work can be attained. Was it St. Augustine of Hippo who said: "How can their corruption become incorruptible, and their mortality become immortal save only if they return to the general body of the congregation"?

As Lord Horder paid me the compliment of referring to me as "a distinguished paediatrician" I feel it is most ungrateful to cavil at his article. But as he quotes me only to disagree I feel bound to defend my credo. I regret that this comment is belated. This is due to circumstances over which I have but recently resumed control.—I am, etc.,

London, W.1. Cicely D. Williams.

Obituary

W. D. H. STEVENSON, C.I.E., M.D.,

F.R.F.P.S., D.P.H.; Lieut.-Col., I.M.S. (ret.)

Lieut.-Col. W. D. H. Stevenson, director of the Government Lymph Establishment, Hendon, and a distinguished member of the staff of the Ministry of Health, died on Nov. 3 at University College Hospital. An honours graduate of Glasgow University and medallist in many subjects, Stevenson joined the Indian Medical Service in 1906 and served on the North-West Frontier in 1906–8 and again in 1915–16. He served also in Mesopotamia in 1916–18, where he did admirable work in the control of dysentery and the enteric infections, for which he received mention in dispatches and was awarded the C.I.E. In 1922–4 he was Assistant Director-General, I.M.S. (Sanitary), and in the latter year was made director of the Pasteur Institute of India at Kasauli—a post he resigned on leaving the service in 1927.

J. R. H. writes:

Stevenson returned to Glasgow and became pathologist to the Glasgow Municipal Hospitals until 1930, when he was appointed to succeed the late Dr. Blaxall at Hendon. His work hitherto had been in the field of general rather than special bacteriology and pathology, but he threw himself into his new work with zest and thoroughly justified his appointment. A good Scot, courteous, loyal, hard-working, and entirely reliable, Stevenson soon became master of his subject, and he and his staff proved equal to any emergency. He was entirely responsible for the manufacture and issue of smallpox lymph for public vaccinators and the fighting Services, and, during the recent war, also for United States troops in this country. This involved a sixfold increase in output—from 400,000 to 2,500,000 doses a year—which could be done only by modifying the method of preparation, which Stevenson, with characteristic care and foresight, had anticipated and was ready for.

To medical literature Stevenson made valuable contributions on rabies, leprosy, malignant melanomata, plague, smallpox and vaccination, and allied subjects. His studies on the cultivation of vaccinia virus on the chorio-allantoic membrane of chick embryos, and dermal strain of vaccinia virus grown on chorio-allantoic membrane of chick embryos, are a model of painstaking and conscientious effort. He leaves a widow, and a son and daughter who have followed him in his own profession.

C. W. ALFORD, M.D.

Dr. Cyril Wolrige Alford, who died on Nov. 2, practised in Chelmsford for 43 years. The son and grandson of a doctor, Alford was educated at Epsom College and Middlesex Hospital, where he had a most distinguished career. He qualified with the Conjoint diploma in 1896, graduated M.B.Lond., with honours in midwifery and medicine, in the following year, and in 1899 qualified for the gold medal in the London M.D. At the Middlesex he held the posts of casualty medical officer, house-physician, obstetric house-physician, and demonstrator of physiology. He also served as Hunterian Prosector at the Royal College of Surgeons. A colleague writes:

Dr. Alford settled in general practice in Chelmsford in 1902 and held many important public appointments. Chief among these was surgeon to the Chelmsford and Essex Hospital. It was here that he did his greatest work, and he served it with untiring energy and devotion until within a few weeks of his death. During his 43 years' service it developed from a comparatively insignificant cottage hospital of 30 beds into a large and flourishing general hospital, and this great progress was in no small measure the outcome of Alford's exertions and foresight. In 1937, when he was approaching the age for retirement from the staff, his colleagues, reluctant to lose his wise counsels, created the post of medical superintendent, which he filled with distinction, and to the great benefit of hospital and staff alike, until the time of his death. In addition to being surgeon to Chelmsford Hospital, he was also consulting surgeon to the Courtauld Hospital, Braintree, and in World War I he served as surgical specialist in the R.A.M.C.

As a surgeon, Alford was sound and resourceful and he loved his work; as a general practitioner, he seemed to prefer to devote his skill and care to the poorer sections of the community, and by them he was greatly beloved; as a man, his outstanding characteristics were his honesty of purpose and his sound common sense. Alford always kept both feet on the ground and he seemed never to take a false step. He displayed wise judgment in all problems that confronted him, whether clinical or administrative, and his advice will be sorely missed by a very wide circle of patients, friends, and medical colleagues. His great industry and devotion to his work left him little leisure for pastimes, but he was an avid reader, a keen gardener, and a great lover of music, being chairman of the Essex Musical Festival for many years. He married Dorothea, daughter of Prebendary D. J. Pring, by whom he is survived. Her grief is shared by all his colleagues, who have lost their elder statesman at a time when he can least be spared, and by countless patients, who had learnt to regard him as "the beloved physician."

R. D. GILLESPIE, M.D., F.R.C.P.

Dr. Arthur Markson writes from Glasgow: It was with an acute sense of personal shock that I learned of the death of Robert D. Gillespie. Prof. D. K. Henderson's appreciation of him is so complete that it would be difficult to add to it, nevertheless I feel impelled to add a personal tribute to a good and valued friend. His professional achievements were of the highest order, and he undoubtedly reached Olympian heights in his own sphere of medicine; yet even in these exalted realms he never forgot his old friends. As is inevitable, I lost touch with him for some time, yet only a few months ago I received a letter from him, in which, though primarily professional, he still found space in his memory to recall "old times." I well remember how at school we shared the joy of resuscitating the *Hutchesonian*, of which we became joint editors, and I can also recall his brilliant article entitled "Caesar: de Germanis," which even in these early days showed that his mind was turning to psychology. Besides being a brilliant Latin scholar, he was very devoted to English literature, especially poetry, and I still treasure a small book of poems he once sent me as a present. His untimely passing at the height of his career has left a sad emptiness to which even with time, the inveterate healer, it will be difficult to become resigned. "Nor in truth," wrote Cicero, "would the honours of illustrious men continue after death, if their own spirits did not make us preserve a longer remembrance of them." Robert Dick Gillespie had indeed a nobility of spirit and loftiness of character which shone through his whole life, giving added distinction to the honours he achieved in medicine, and we shall not forget him. *Ave atque vale!*

Mr. D. Harcourt Kitchin writes: I was shocked to read of R. D. Gillespie's death at such an early age. The writer of your obituary notice, good though this is, makes no mention of one feature of Gillespie's work which always impressed me. I sometimes saw him give expert evidence in the courts. He not only made an excellent impression by his immaculate dress, but he managed to deal with extremely difficult questions of forensic psychiatry with such impartiality and dignity, and to display such a wealth of first-hand knowledge, that he must have added greatly to the reputation of expert witnesses in general. He always seemed to me to be a shining example of what a medical witness ought to be.

Dr. **JOHN FOSTER BEALE**, who died at Folkestone on Oct. 19 aged 67, had been bacteriologist to the Essex County Council and consulting analyst and bacteriologist to the Port of London. A native of Monks Kirby, Warwickshire, he was educated at Malvern College, Clare College, Cambridge, and the London Hospital, qualifying M.R.C.S., L.R.C.P. in 1904 (followed by the D.P.H. in 1905), and taking his M.A. in 1927. Dr. Beale began his career in sanitary science as demonstrator of public health at the London Hospital, and was then assistant M.O.H. for the City of Westminster and for Essex before his appointment as bacteriologist to the Essex County Council and to the Willesden Urban District Council, and joint director of the Counties Public Health Laboratories in Queen Victoria Street, E.C. He published a number of papers on water examination and on water-borne diseases, and the book by Dr. J. C. Thresh and himself, *Simple Method of Water Analysis*, reached its tenth edition in 1931. W. A. B. writes: The sudden death of Dr. John F. Beale came as a great shock to all his old colleagues in Essex. His first contact with Essex arose when he became assistant to Dr. John C. Thresh, the first county medical officer of health, little dreaming that it was the commencement of a long partnership. Thus over 30 years ago he acquired a detailed knowledge of the highways and byways of Essex, and from a good master learnt the rudiments of preventive medicine. That period of apprenticeship shaped his career. He had found the work he loved, and he never spared himself in the war against disease and in the efforts to improve and safeguard the health of the people. Out of all this grew the combination of Thresh and Beale, serving the general public through the Counties Public Health Laboratories. The regulations which Beale drafted as bacteriologist for Essex at the inception of the scheme are still in operation except for modifications required by changes in the service. He laid down for the county arbitrary standards for water supplies, sewage and trade effluents, non-designated milk and ice-cream, all of which are still operating. He showed keen interest in field work and rendered invaluable assistance to local medical officers of health, surveyors, and sanitary inspectors. When public and private swimming pools were being opened in increasing numbers he appreciated and acted on the necessity for safeguarding the general public. Subsequently "Thresh and Beale" became "Thresh, Beale, and Suckling," to be followed by "Beale and Suckling," which partnership continued until March, 1938, when Dr. Beale retired. Readers of medical and technical journals owe much to the many contributions he made from time to time. He is perhaps remembered most of all by the 3rd and 4th editions of *The Examination of Water and Water Supplies*—in the former jointly with the late Dr. John C. Thresh, and in the latter with the late Dr. E. V. Suckling. The popularity and usefulness of this monumental work are proved by the fact that each edition went quickly out of print. His charming, kindly disposition appealed to everyone—he was more than a public servant; rather was he a public benefactor.

Dr. **RICHARD WOODWARD HIGSON**, of Bolton, died on Oct. 4 after an illness lasting four months. He was educated at Manchester Grammar School, and in 1905 graduated M.B., Ch.B. Victoria from Owens College, Manchester. He had been in practice at Bolton for the past 40 years, during which time he was medical referee for the Lancashire and Cheshire miners; he was also a Poor Law medical officer for 35 years, and carried on a large panel and private practice. Dr. Higson, who joined the British Medical Association in 1913, leaves six children—three sons and three daughters.

We regret to record the death on Oct. 23 of Dr. **JOSEPH RICKARDS**, of Brackley, Northants, at the age of 63. A native of Manchester, he had been educated at Owens College, and obtained the degrees of M.B., Ch.B., and B.Sc. of Victoria University. After holding assistantships at Ashton-under-Lyne and in South Wales, he took over a practice at Aynho, Northants, and after war had broken out in 1914 he joined the

Derby Scheme and was called up in 1916. He was attached to the Royal Scots, and at the Battle of Arras he won the Military Cross, being later taken prisoner. On his release he returned to his practice at Aynho. Since then he had done a large amount of lecturing for the British Red Cross Society in many places, and also lectured on anti-gas. The last eight years of his life were spent in the adjoining town of Brackley, where he had an extensive practice. He was medical officer for the Public Assistance Committee and also of the Brackley Cottage Hospital. In addition he had been borough coroner for Banbury, Oxon, for about ten years. Dr. Rickards was a keen musician, noted for his organ-playing in the district. He had been a member of the B.M.A. for 40 years.

A very learned man in his special field of study, Dr. **John Smyth Crone**, deputy coroner for West Middlesex 1916–39, and for a year Sheriff of Middlesex, died at Ealing on Nov. 6. He was born in Belfast on Nov. 25, 1858, and was educated at the Royal Academical Institution, at Queen's University, Belfast, and at the London Hospital. He qualified in 1882, and during 40 years' practice in Willesden he became widely known as an authority on Irish literature and history and a whole-hearted bibliographer. He was a member of the Irish Literary Society of London from its foundation in 1892, and its president for seven years, a Fellow of the Royal Society of Antiquaries of Ireland, and a member of the Royal Irish Academy. He founded and edited for 15 years a monthly magazine, *The Irish Book Lover*; wrote a book on the life and work of Henry Bradshaw, the famous librarian of Cambridge University; and compiled a *Concise Dictionary of Irish Biography* which stands as a memorial to his industry and enthusiasm. Dr. Crone was a J.P., had been chairman of the Willesden District Council, a member of the Middlesex County Council, chairman of the Willesden Division of the B.M.A., and president of the Willesden Medical Society.

Lieut.-Col. **Ernest Frederick Gordon Tucker**, I.M.S. (ret.), died on Nov. 11 at Oxford, where he had served during the war as chairman of the Medical Recruitment Board. Born in 1869, he studied medicine at St. Mary's and the London Hospitals, qualified in 1895, and took the M.B., B.S.Lond. degrees (with distinction in surgery) in 1909, and the M.R.C.P. in 1910. During his period of service in the I.M.S. Col. Tucker was senior physician to the J.J. Hospital, and professor of medicine at the Grant Medical College, Bombay, and had served with the China expedition of 1900. He published a paper in 1904 on the management of a plague epidemic. After his retirement he lectured for a time in tropical hygiene for the I.C.S. Delegacy at Oxford, and became a member of the university, taking the B.Sc. and B.A., and the M.A. in 1932. He joined the British Medical Association in 1904, and acted as representative at the Annual Meeting at Aberdeen, which broke up just before the declaration of war in August, 1914; he gave up membership two years ago on account of failing health.

Dr. **William Young Woodburn**, who died at Southsea on Nov. 13 aged 66, was associated with the Royal Portsmouth Hospital for 26 years, having been appointed honorary assistant physician in 1919 and promoted to the senior staff in 1937. He undertook in addition to his other duties the charge of the out-patients clinic for treatment of rheumatism at the hospital; he was also medical officer to the Royal Naval and Marine Orphans' Home for over thirty years. Dr. Woodburn, a native of Australia, studied medicine first in Melbourne and then in Edinburgh, graduating M.B., Ch.B.Ed. in 1903, and proceeding M.D. in 1906. In the war of 1914–18 he served with the R.A.M.C., and from the time of the outbreak of war in September, 1939, he remained on duty in Portsmouth and worked there throughout all the air raids. A keen cricketer, who bowled with much success up to the age of 54, Dr. Woodburn was also a good shot, played a useful round of golf, and was a formidable opponent at lawn tennis. In professional life his thoroughness and devotion to duty, combined with great sympathy, endeared him to all his patients. He joined the B.M.A. in 1911, and at the Portsmouth Annual Meeting in 1923 was secretary of the Section of Tuberculosis.

Dr. **George Herbert Lancashire**, consulting physician to the Manchester and Salford Hospital for Skin Diseases, and formerly lecturer on dermatology in the University of Manchester, died on Nov. 20 at Alderley Edge. He was born in 1866, and from Manchester Grammar School went to study medicine at Owens College, qualifying M.R.C.S., L.R.C.P. in 1890 and taking the Brussels M.D. in 1901, after a period of study in Vienna. From 1895, when he was elected to the honorary staff of the Manchester and Salford Skin Hospital, he devoted himself entirely to dermatology. He published numerous articles on his specialty, and translated from the German Dr. L. Freund's *Elements of General Radio-Therapy* in 1904. He joined the B.M.A. in 1896, and held office as secretary in 1902, vice-president in 1922, and president in 1929, of the Section of Dermatology when the Association met in Manchester. He became a member of the Dermatological Society of London in 1902, and was elected a Corresponding Member of the Dermatological Society of Vienna.

The death of Dr. **David F. Todd** removes a vigorous personality who for many years took an active part in the work of the British Medical Association, both in the North-East of England and at headquarters in London. He studied medicine in Belfast and Edinburgh, took the Scottish triple qualification in 1890, and settling in practice at Sunderland became surgeon to the Sunderland Dispensary and medical referee under the Workmen's Compensation Act. During the war of 1914–18 he served as temporary major, R.A.M.C., attached to the 3rd Northumberland Brigade, R.F.A., and as medical officer in charge of troops and medical inspector of recruits. David Todd joined the B.M.A. in 1897, and represented the Sunderland Division at no fewer than twenty-three Annual Meetings between 1905 and 1939; he was also for three periods a member of the central Council and served on the Naval and Military Committee, the Finance Committee (five years), the Medico-Political Committee (five years), and the Contract Practitioners Subcommittee. In November, 1922, he stood, without success, at the General Election as Unionist candidate for the Parliamentary Division of Chester-le-Street; in the following year he was elected chairman of the Durham County Insurance Committee, and in 1925 became a member of the Health Committee of the Durham County Council. He held office as president of the North of England Branch of the B.M.A. in 1924–5. His last appearance at an Annual Representative Meeting was in Aberdeen five weeks before the outbreak of war. Death has taken toll of the friends he used to meet year by year at the A.R.M., but many survive to mourn his passing.

Dr. **Ghulam Hussein** Pirmohamed died in Zanzibar on Jan. 19, 1945. Born at Karachi, India, on Nov. 20, 1896, he studied medicine at Grant Medical College, University of Bombay, and obtained his M.B., B.S. degrees in 1922. He practiced medicine for three years in Bombay, and later took up the appointment as a physician in charge of the Nasser Noormohamed Charitable Dispensary, Zanzibar, in 1925, which position he resigned in 1941 to start his own practice. Dr. Ghulam Hussein was for many years an active member of the Zanzibar Maternity Association and was also appointed unofficial member of the Liquor Licensing Court on many occasions. He was a member of the B.M.A. As a physician he had established a high repute, and his loss has been keenly felt in Zanzibar. He leaves a widow and six children, with whom much sympathy is felt.

The following well-known medical men have died abroad: Dr. **Hugh Cabot**, the eminent surgeon of Boston, U.S.A., aged 73: Dr. **David Linn Edsall**, emeritus Jackson professor of clinical medicine at Harvard Medical School; Dr. **Froehlich**, honorary professor at the Nancy Faculty of Medicine; Dr. **L. Delrez**, professor of surgery at Liège; Dr. **Paul H. Valdervehr** a prominent physician of Brussels; Dr. **William Ningen**, an outstanding surgeon of Hungarian birth and emeritus professor of surgery at Long Island College, aged 72; Dr. **Juan N. Corpas**, a distinguished surgeon of Colombia, formerly rector of the National Faculty of Medicine at Bogota and professor for many years in the general and surgical clinic of the same faculty and ex-Minister of Education; Dr. **Roberto Salé**, a distinguished surgeon and anatomist of Buenos Aires, and honorary professor in the University and ex-president of the Buenos Aires Academy of Surgery.

The Services

Surg. Lieut.-Cmdr. K. J. R. O'Connor, R.N., and Temp. Acting Surg. Lieut.-Cmdr. T. B. Fitzgerald, D.S.C., R.N.V.R., have been mentioned in dispatches for bravery, skill, and endurance while serving in certain of H.M. ships in mine-sweeping operations and the bombardment, supported by air strikes, of Japanese airfields in Puket Island, Salang, during July, 1945.

CASUALTIES IN THE MEDICAL SERVICES

Died.—Surg. Cmdr. Archibald Hamilton Douglas Ord Richmond, R.N.V.R.

Died in a prison camp in Malaya.—Capt. Henry Alexander Deverell, R.A.M.C.

Died in a prisoner-of-war camp, Borneo.—Capt. Kenneth Daniels, R.A.M.C.

Universities and Colleges

ROYAL COLLEGE OF SURGEONS OF ENGLAND

ANNUAL MEETING OF FELLOWS AND MEMBERS

The annual meeting of Fellows and Members of the Royal College of Surgeons of England was held on Nov. 15, Sir **ALFRED WEBB-JOHNSON**, Bt., presiding. In submitting the report of the Council for the year ended July 31 last, the President referred at length to the proposal for bringing the three Royal Colleges together on one site—a matter, he said, which interested not only their own College but the whole medical profession and a considerable section of the public. The Council of the Royal College of Surgeons had pledged the funds of the College to the extent of £100,000 to provide the opportunity, and if the opportunity was missed it would not be their fault. What they had done meant a considerable sacrifice—namely, the loss of income on that sum year after year—but they thought it their duty to keep the opportunity open.

He then read correspondence on the subject with the Royal College of Physicians, who had written on Oct. 23 stating that they had come to the conclusion that their interests would best be served by remaining in their present premises in Trafalgar Square. A further letter, at the request of the Council of the Royal College of Surgeons, had been forwarded to Lord Moran, P.R.C.P., stating that in spite of this decision it was hoped that the Comitia would consider very seriously whether the future of academic medicine in this country would not best be served by having their buildings in close proximity. In 1941 the governing body of each of the Colleges had affirmed that the desirability of bringing the three Colleges into close proximity was of "infinitely greater importance than that of attachment to any particular site." The letter continued:

> "The Fellows and Members of this College [of Surgeons] have consistently supported the plan for contiguous College buildings because they have felt that there were much bigger issues involved than the immediate interests of their own College. They consider that, in order to secure and retain the confidence of the Government and people, the representative academic medical institutions must be able to advise the State with a single authoritative voice, and that they can do this more effectively from a common centre. Moreover, a medical academic centre, in which each College would retain its identity, would have great imperial and international influence. It would be a centre of research and learning. It would be able to maintain liaison with the Dominions and foreign countries, to arrange and conduct international congresses, and provide for the organization of research and the publication of standard medical literature in foreign languages."

It was added that the plans for the restoration and development of the Royal College of Surgeons included many facilities which would gladly be placed at the disposal of the sister colleges. "While financial considerations and the present interests of each college may determine a decision on a short view, my Council feels that the big question of future policy requires a different approach." The present opportunity would be kept open by the retention of the properties already acquired in the hope that on future consideration the Comitia of the R.C.P. would decide to co-operate, and no negotiations would be entered into to dispose of the sites for other purposes without information first being given to the other Royal Colleges.

The meeting passed unanimously a resolution approving the action of the Council in the matter.

The Proposed National Health Service

The **PRESIDENT** went on to refer to the proposals for a National Health Service. The Council, which had debated this matter on several occasions, had considered it from the point of view of what would be best for the people, without any consideration of vested interests. When they talked about the freedom of the profession it was not vested interests they had in mind, but the fundamental right of a free people to get independent professional opinion. Rumours as to the character of the new service were flying about; he hoped they were not well founded, because a service so set up would not be in the best interests of the people. It would be well not to go into detail when so much was uncertain, but to confine themselves to two fundamental principles which must not be outraged if a satisfactory service was to be forthcoming. The first was the freedom of the profession, and the second that there must be a real partnership between the administrators of the service and those who actually carried out the treatment of the patients.

Mr. **CYRIL E. BEARE** proposed:

(1) That this meeting is of opinion that in any proposed National Medical Service no hospital shall be prevented from carrying out such work as its medical staff can efficiently perform in that hospital;

(2) That this meeting is of opinion that the efficiency of the work done and not the number of beds in a hospital is of primary importance in any National Medical Service.

He was concerned at the course which might be adopted with regard to the smaller hospitals, that the Government might offer to leave the large teaching hospitals in an independent position, provided the smaller hospitals were placed under the control of local authorities. It was to the advantage of both the public and the profession that the voluntary hospitals, both large and small, should survive, and that the place of the hospital in the medical service should be determined not by its size or the number of its beds but by the efficiency of the work done and the ability of its staff to provide the service which the patients demanded.

The **PRESIDENT** said that the resolutions were such as could generally be accepted. He assured Mr. Beare that the Council and the members of the staffs of the teaching hospitals were just as anxious to preserve the non-teaching voluntary hospitals as the staffs of those hospitals themselves, and the point was rather covered by the general principle that there should be a true partnership between the administrators and the profession. There could not be a better example of such partnership than a well-run voluntary hospital. With regard to the second resolution, the corporate body of surgeons from the earliest times had been concerned with the quality of the practice of surgery by ensuring that those who practised it were qualified to do so and by maintaining a proper code of ethics among practitioners. Admittedly the Government was concerned with quantity and distribution, but quality was the particular concern of the College.

The resolutions were unanimously carried and the proceedings ended.

UNIVERSITY OF LONDON

Kenneth Mellanby, Sc.D.Camb., Ph.D.Lond., has been appointed to the university readership in entomology tenable at the London School of Hygiene and Tropical Medicine from Oct. 1, 1945. Dr. Mellanby was engaged in research at the London School of Hygiene and Tropical Medicine in 1930–6, and was elected Sorby Research Fellow of the Royal Society in 1936. He joined the R.A.M.C. in 1943, but was released in 1944 to proceed to South-East Asia for research on behalf of the Medical Research Council.

UNIVERSITY OF EDINBURGH

Dr. Douglas Guthrie, consulting aural surgeon to the Royal Hospital for Sick Children, Edinburgh, whose recent book, *A History of Medicine*, was reviewed in these columns on Nov. 3 (p. 606), has been appointed lecturer on the history of medicine in the University of Edinburgh, in succession to the late Dr. J. D. Comrie.

WELSH NATIONAL SCHOOL OF MEDICINE

Postgraduate Courses for Demobilized Medical Officers

Provided there are sufficient candidates, a fortnight's concentrated course of instruction for demobilized medical officers will be held at this School of the University of Wales from Jan. 14, 1946, and, in addition, a special week-end course in paediatrics will begin on Friday, Jan. 11. Demobilized medical officers may attend both the week-end course and the fortnight's concentrated course, but the Government grant and allowances will be available for one of the courses only, a fee for the other being charged by the School. Applications to attend the above courses should be received by the secretary, Welsh National School of Medicine, 10, The Parade, Cardiff, not later than Saturday, Dec. 22.

ROYAL COLLEGE OF PHYSICIANS OF EDINBURGH

At a quarterly meeting of the College, held on Nov. 6, with the President, Dr. A. Fergus Hewat, in the chair, Dr. A. J. Murray Drennan (Edinburgh) and Dr. William Forbes (Edinburgh) were introduced and took their seats as Fellows of the College. Dr. Angus MacNiven (Glasgow), Dr. J. S. Fulton (Glasgow), and Dr. W. D'A. Silvera (Jamaica) were elected Fellows of the College.

The Hill Pattison-Struthers bursary in anatomy and physiology was awarded to David Bull.

The Oct.–Nov. number of the *Austrian Medical Bulletin* is published at 1s. 6d. by the Association of Austrian Doctors in Great Britain, 14, Craven House, Kingsway, W.C.2. The contents include an article by Dr. H. S. Baar on hyperchromic anaemias, and a plan by Dr. Robert Schnitzer for a modified E.M.S. hospital for emergency work in Austria; also medical notes on current events and reconstruction work in Austria.

Medical Notes in Parliament

Atomic Energy: Three Powers' Statement

Mr. Herbert Morrison on Nov. 15 announced the decisions made in Washington between Mr. Truman, Mr. Attlee, and Mr. Mackenzie King on the control of atomic energy. This statement declared that the three Powers possessing the knowledge essential to the use of atomic energy were willing to proceed with exchange of fundamental scientific information and interchange of scientists and scientific literature with any country which would fully reciprocate. It added: "We believe that the fruits of scientific research should be made available to all nations and that freedom of information and freedom of ideas are essential to the progress of knowledge."

Scottish Public Health Bill

The Public Health (Scotland) Bill, which has passed the House of Lords, came up for second reading in the House of Commons on Nov. 13. Mr. Buchanan said the Bill provided for medical control at airports in Scotland and brought up to date and consolidated the control which already existed. It brought the provisions into line with the corresponding provisions for England, but conferred no new powers on the Secretary for Scotland except for making regulations for medical control of airborne traffic. The English authority received these powers in 1936. The Department had taken the opportunity to bring up to date the whole code of the Scottish Public Health Acts which dealt with the powers of the Secretary of State to make regulations for preventing the spread of epidemic, endemic, or infectious disease. Previous Acts were now 50 years old. A few obsolete provisions were to be dropped.

Mr. J. S. C. Reid remarked that under the Bill it would be competent to deal with all the mixed questions—venereal disease, vaccination, milk supplies. It would be possible to remodel the regulations on the first and the law about the other two. Cmdr. Galbraith said that under the Bill the Secretary of State could make regulations of any kind. Any disease which was common among the people could be included as endemic.

Mr. Buchanan offered an assurance that the Government did not seek more than the 1897 powers.

The Bill was read a second time.

Scholarships for Medicine.—Replying to Mr. Somerville Hastings on Oct. 18 Miss Wilkinson said State scholarships and major awards by local education authorities could be held for the study of medicine or dentistry. These were the only awards with which the Ministry of Education was concerned. The figures available did not show what proportion of the total number of students were in receipt of such scholarships.

"Wartime" Nurseries.—In reply to Mrs. Castle on Oct. 29 the Minister of Health stated that the existing financial arrangements for wartime nurseries would continue until March 31, 1946. He would shortly be asking welfare authorities how a comprehensive nursery service—comprising nursery schools, nursery classes, day nurseries, and other measures—could best be organized, using existing services as a basis, to meet the needs of their areas. As from April 1, 1946, he proposed a weighted 50% Exchequer grant, comparable to that payable to local education authorities for nursery schools and nursery classes, to be payable to welfare authorities on their approved expenditure on such facilities as they might provide as part of such a nursery service.

Nurses' Salaries.—Mr. Buchanan announced that the Scottish Nurses' Salaries Committee is considering a revision of the salary scales of nurses in Scotland. Prof. T. M. Taylor had resigned from the chairmanship because of pressure of other work, and Mr. John Wheatley had offered his services as chairman.

Special Hospital for Disseminated Sclerosis.—Squad. Ldr. Segal suggested on Nov. 1 that the Minister of Health should arrange for a special hospital to be allocated for the care and investigation of patients suffering from disseminated sclerosis. Mr. Bevan said segregation in a specialized hospital would not necessarily be in the interest of this type of patient. Moreover, it would add considerably to nursing difficulties, and in the present shortage of hospital staff this could not be contemplated.

Rheumatic Fever Notification.—On Nov. 1 Dr. Comyns asked Mr. Bevan to consider including rheumatic fever among the list of compulsorily notifiable diseases to permit of its early diagnosis before heart disease had taken hold. Mr. Bevan replied that he was aware of the evil consequences of rheumatic fever. The whole problem of how best to fight this disease was being intensively examined and the question of notification would not be overlooked.

Research in Rheumatism.—Mr. Bevan stated on Nov. 15 that a number of universities and teaching hospitals had been approached to set up diagnostic and research centres for the study of rheumatic conditions. Progress had been slow because of the shortage of medical and nursing staff.

Compensation for Pneumoconiosis.—The Workmen's Compensation (Pneumoconiosis) Bill was read a first time in the House of Commons on Nov. 14. It provides for periods of war service or war employment to be disregarded for certain time limits in schemes under the Workmen's Compensation Act, 1925.

Silicosis in Rhodesian Copper Mines.—Mr. George Hall stated on Nov. 14 that the presence of silicosis in some mines in Northern Rhodesia was established as the result of an inquiry by medical experts in 1943. In that year a committee was set up to examine and advise on certain aspects of the problem. As a result of the committee's recommendations the Silicosis (Temporary Arrangement) Ordinance had been passed, which provided for the establishment of a Silicosis Bureau, the regular medical inspection of miners, the payment of compensation to miners who contracted the disease in the Northern Rhodesia Mines, and the cessation in certain circumstances of work as miners by those who contracted the disease.

Liquid Paraffin Shortage.—Mr. Bevan told Sir E. Graham-Little on Nov. 15 that he knew of the shortage of potable liquid paraffin. The matter was engaging his attention and that of the Minister of Fuel and Power and the Minister of Supply. The treatment or use of liquid paraffin conforming to the *British Pharmacopoeia* specification for any purposes other than medicinal purposes, except under the licence granted by the Minister of Fuel and Power, was prohibited by the Control of Petroleum Order, 1944.

Notes in Brief

On Oct. 17 Mr. Wilfred Paling, Minister of Pensions, refused to bring artificial limbs under price control. He pointed out that each artificial limb was made and fitted to an individual's requirements, so that its production and maintenance services did not lend themselves to control.

The lymph made at the Government Lymph Establishment is derived from seed lymph obtained from Cologne. Rabbits are used in the reinvigoration of the lymph.

Medical services in the West Africa Command are being reorganized. Considerable reductions in medical and nursing staff are being made.

Medical News

Dr. Cecil Wall's Fitzpatrick Lectures before the Royal College of Physicians, announced for Dec. 11 and 13, have been postponed.

A joint meeting of the Society of Public Analysts and Other Analytical Chemists with the Food Group of the Society of Chemical Industry will be held at the rooms of the Chemical Society (Burlington House, Piccadilly, W.) on Wednesday, Dec. 5, at 6.15 p.m., when there will be a discussion on "New Routine Tests and their Application in Modern Food Industry."

Dr. W. J. O'Donovan will deliver a lecture on "The Most Modern Dermatological Treatments" before the Whipps Cross Hospital Medical Society at the hospital on Friday, Dec. 7, at 8.30 p.m.

Sir Joseph Barcroft, F.R.S., will deliver the Harben Lectures for 1945 before the Royal Institute of Public Health and Hygiene on "The Respiratory Function of the Blood" at 28, Portland Place, W., on Dec. 10, 11, and 12, at 3 p.m.

The British Institute of Philosophy has arranged a lecture to be given by Dr. Russell Brain on "The Neurological Approach to the Problem of Perception" at University Hall, 14, Gordon Square, W.C.1, on Friday, Dec. 14, at 5 p.m. This is the first Manson Lecture on "Philosophy and Medicine," and medical men and women will be welcomed.

At a meeting of the Court of Directors of the Society for Relief of Widows and Orphans of Medical Men, held on Oct. 10, with the president, Dr. R. A. Young, in the chair, the audited accounts for the half-year ended June 30 were presented and approved. During the period £2,002 10s. had been granted as relief to 55 widows; a legacy of £5,000 had been invested in 2½% Consols; £251 2s. 6d. had been received in subscriptions; and the expenses amounted to £197 19s. Membership of the society is open to any registered medical man who at the time of his election, which is by ballot, is resident within a twenty-mile radius of Charing Cross. Relief is granted only to necessitous widows and orphans of deceased members. Full particulars may be had from the secretary at 11, Chandos Street, Cavendish Square, W.1.

On Oct. 20 the Association of Scientific Workers held a meeting to consider "the interrelations between the social and the natural sciences," with Sir Robert Watson Watt, F.R.S., in the chair. The meeting resolved to set up a Joint Sciences Committee to consider the best ways in which natural and social scientists can be brought together to deal with social problems, and to consider certain fields in which such work is of particular importance.

Dr. Ruth Young, late Principal of the Lady Hardinge Medical College, New Delhi, is visiting Egypt, Palestine, and Syria for two months, under the auspices of the British Council, to lecture on child welfare and British achievements in that field.

Dr. T. P. Feng, an eminent Chinese physiologist, has arrived in this country for a stay of some months under arrangements made by the British Council, in collaboration with Prof. A. V. Hill, Secretary of the Royal Society. After visits to the Physiology Departments in the Universities of Oxford, Cambridge, Edinburgh, and Bristol, Dr. Feng will work in laboratories and libraries. A graduate of Fuhtan University, he spent three years here and gained the degree of D.Ph. at the University of London in 1933, and was elected a member of the Physiological Society. On his return to China Dr. Feng became associate professor of physiology in Peking Union College, and latterly has been professor of physiology in the Shanghai Medical College, temporarily in Chungking, and technical director of the Medical Research Institute, which he organized.

The Treasury has made an Order entitled "The Purchase Tax (Exemptions) (No. 2) Order, 1945," the effect of which is to exempt from Purchase Tax a large number of drugs and other medicinal products which are specified in a schedule. In general the new Order amplifies and in some respects recasts the list of drugs already exempt. A revised Notice No. 78 B incorporating in a single schedule all the exempt drugs will shortly be issued and a copy will be supplied to all registered traders likely to be concerned.

The Provisional National Council for Mental Health (39, Queen Anne Street, W.1) has lately appointed Col. K. Soddy, M.D., to the medical directorship of the National Association for Mental Health. Col. Soddy has, since September, 1943, acted as deputy director of selection of personnel and chief technical officer, India Command, and is still serving in that capacity. The appointment was made in the candidate's absence over-seas, and will be taken up as soon as he secures his release from the Army.

The Home Nursing Scheme for Greater London, which was noted recently in these columns, has prepared a small pamphlet giving a list of telephone numbers of district nurses in the London area. The organizing secretary (19, Hammersmith Broadway, W.6) will supply a copy to any doctor or hospital on receipt of an application with a 2d. stamp to cover cost of printing and postage.

The Minister of Health has supplied to hospitals owned by county councils and county borough councils, joint boards for tuberculosis and joint sanatorium boards, copies of the second memorandum on hospital diet issued by King Edward's Hospital Fund for London. The first memorandum was noticed in the *Journal* of Sept. 18, 1943 (p. 365), and the second on Sept. 8, 1945 (p. 328).

EPIDEMIOLOGICAL NOTES

Discussion of Table

In *England and Wales* the only changes in the incidence of infectious diseases were decreases in scarlet fever and measles, of 198 and 51 respectively, and an increase of 77 in cases of whooping-cough. The incidence of scarlet fever notifications went down slightly in most areas, except in the north, where the trend remained practically constant. The largest falls in scarlet fever were in Warwickshire (46) and in London (36). The chief feature of the diphtheria returns was a fall of 31 in Lancashire; the largest rise was in Durham (11). Only small fluctuations occurred in the local trends of whooping-cough; the increase was mainly due to small rises in the southern part of the country. The trend of measles showed a change only in Wales, where there were 45 fewer cases. Notifications of dysentery were 1 more than in the preceding week. The only fresh outbreak of any size was in Kent, Maidstone M.B. 19. The other large returns were Lancashire 34, London 34, Yorks West Riding 20, Glamorganshire 19, Caernarvonshire 14, and Warwickshire 10.

In *Scotland* the incidence of diphtheria decreased by 31 cases, and dysentery by 15, while measles rose by 37. The fall in diphtheria occurred in the western area. The reduction in dysentery took place mainly in Glasgow, where the cases fell from 52 to 37.

In *Eire* 16 fewer cases of diphtheria were recorded, while whooping-cough, scarlet fever, and measles were slightly more prevalent, with rises of 24, 7, and 7 respectively. Forty-three further cases of diarrhoea and enteritis were recorded in Dublin C.B., being 6 fewer than last week. Practically all the cases of measles, and more than half the cases of whooping-cough, were notified in this city.

In *Northern Ireland* the only change in the totals was a decrease of 13 in scarlet fever.

Week Ending November 17

The notifications of infectious diseases in England and Wales during the week included: scarlet fever 1,674, whooping-cough 1,203, diphtheria 646, acute pneumonia 420, measles 403, dysentery 180, cerebrospinal fever 36, acute poliomyelitis 32, paratyphoid 1, typhoid 1.

No. 45

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended Nov. 10.

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for: (a) England and Wales (London included). (b) London (administrative county). (c) Scotland. (d) Eire. (e) Northern Ireland.

Figures of Births and Deaths, and of Deaths recorded under each infectious disease, are for: (a) The 126 great towns in England and Wales (including London). (b) London (administrative county). (c) The 16 principal towns in Scotland. (d) The 13 principal towns in Eire. (e) The 10 principal towns in Northern Ireland.

A dash — denotes no cases; a blank space denotes disease not notifiable or no return available.

Disease	1945					1944 (Corresponding Week)

Rate per 1,000 total births (including stillborn)			37					33		

* Measles and whooping-cough are not notifiable in Scotland, and the returns are therefore an approximation only.

† Includes primary form for England and Wales, London (administrative county), and Northern Ireland.

‡ Includes puerperal fever for England and Wales and Eire.

§ Owing to movements of population, birth and death rates for Northern Ireland are still not available.

Letters, Notes, and Answers

All communications with regard to editorial business should be addressed to The EDITOR, British Medical Journal, B.M.A. House, Tavistock Square, London, W.C.1 Telephone: EUSTON 2111. Telegrams: *Aitiology Westcent, London* ORIGINAL ARTICLES AND LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated.

Authors desiring REPRINTS should communicate with the Publishing Manager, B.M.A. House, Tavistock Square, W.C.1, on receipt of proofs. Authors over-seas should indicate on MSS. if reprints are required, as proofs are not sent abroad.

ADVERTISEMENTS should be addressed to the Advertisement Manager, B.M.A House, Tavistock Square, London, W.C.1 (hours 9 a.m. to 5 p.m.). Telephone: EUSTON 2111. Telegrams: *Articulate Westcent, London.*

MEMBERS' SUBSCRIPTIONS should be sent to the SECRETARY of the Association. Telephone: EUSTON 2111. Telegrams: *Medisecra Westcent, London.*

ANY QUESTIONS?

Incontinence in the Elderly

Q.—*A single woman of 76 begins to lose control of her bladder. What might be the cause of this?*

A.—There are many possible causes, and a lesion of the nervous system should be first excluded, bearing in mind that the lesion may be an early one, with disturbance in urination as its first symptom. Another possibility is organic disease within the bladder or urethra. Any tumour in the lower abdomen or pelvis might disturb bladder control, and conditions such as nulliparous prolapse, diseases of the cervix and vagina, urethral caruncle, etc., should also be kept in mind. A very full investigation of the nervous and genito-urinary systems is indicated, but if an organic lesion is not found, then the loss of control could be explained by senile atrophy of the muscles of the sphincter mechanism. Such a condition is not rare, and at the age of 70 its treatment is likely to be difficult. Incontinence of this type was dealt with very fully in an answer to a question published in the *Journal* on Jan. 27, 1945 (p. 139), and reference to this should be made.

Fleas in the Laundry

Q.—*As medical officer to a laundry I am looking for a preparation to be applied externally, or taken internally, which will repel fleas. It is impracticable to disinfest the bundles of clothing before the fleas jump out on the sorters. Apparently D.D.T. is unlikely to stop this immediate jumping out. I have tried sulphur gr. 5 t.d.s. on one subject over several days, but this had no effect, and the ordinary proprietary creams were also ineffective.*

A.—We do not know of any substance which, taken internally, will prevent insect-bites. The most effective repellants for external application act mainly by being irritant or paralysing to the insect on contact—e.g., dimethyl phthalate, indalone, pyrethrum preparations, etc. These will prevent an insect's walking over skin or garments on which they are smeared.

Since it is clearly impossible to apply such materials all over the body of the laundry sorter, they must obviously be combined with protective clothing. Overalls with trousers and sleeves are desirable. The cuffs and trouser ends should be tightly fastened and repellant applied liberally to the garments in these regions and also at other openings to the body.

Chronic Recurrent Parotitis

Q.—*A man of 76, in good health but deaf, has obstruction to the flow of saliva from both parotid glands. The stoppage, on one side or the other, lasts for hours, with gradually increasing pain and swelling of the gland. Eventually there is a gush of secretion into the mouth, and relief. The ducts have been probed but no calculus located. Various methods of applying heat during the acute attack have been used and help to relieve the pain and to overcome the resistance to the flow of saliva, but the condition recurs. Is there any possible connexion between the trouble in the gland and the chronic deafness—possibly interference with nerve control?*

A.—The condition described in this patient is almost certainly one of chronic recurrent parotitis, and as it is bilateral it is most unlikely that it is associated with parotid calculi. Confirmation of the diagnosis may be obtained by examination of a specimen of saliva taken directly by a glass cannula from the parotid duct. This saliva may show turbidity due to the presence of numerous blobs of muco-pus, or a uniform turbidity. Cytological examination will show many pus cells and columnar or pavement epithelial cells, often containing bacteria. The commonest infecting organisms in this type of parotitis are the *Str. viridans* or the pneumococcus. A sialogram with the injection of lipiodol will give detailed information about the degree and type of dilatation of the duct system. The catarrh and infection are present in the ducts all the time and the acute attacks are due to blockage of the larger ducts with tenacious muco-purulent secretion. It is unlikely that there is any connexion between the parotitis and the deafness, and unlikely that there is any interference with nerve control.

At the age of 76 drastic measures hardly seem called for, and the simplest procedure is to show the patient how to empty each gland digitally. In the case of the right parotid the index and middle fingers of the patient's right hand are placed firmly on the left side of the chin and the thumb over the right parotid gland. The gland is then stroked firmly with the thumb in a forward direction towards the angle of the mouth. The first stroke is started at the tragus of the ear, the second at the lobule, and the third just behind the angle of the jaw. Each forward movement of the thumb should be firm and deliberate and take about half a minute to reach the angle of the mouth. This manœuvre should be carried out for five minutes on each side first thing in the morning and last thing at night. It will help to keep the gland empty of tenacious secretion and will usually avert the acute attacks. Other methods of treatment include dilating the ducts with graduated probes, deep *x*-ray treatment in the case of *Str. viridans* infections, and in the worst cases a plastic operation on the duct. Mastication is the most important single factor in inducing the flow of saliva and in emptying the parotid glands. In almost all cases of chronic recurrent parotitis there is some impairment in the efficiency of the chewing mechanism as the result of missing teeth, ill-fitting dentures, etc.

Lupus Vulgaris

Q.—*An otherwise apparently healthy girl of 15 has a patch of lupus on the cheek and is having out-patient treatment. Her work consists of (1) helping in a grocery shop, and (2) looking after the grocer's three children, one a baby of a few months. She "lives in." Ought she to continue with either of these two jobs, and if so what precautions, if any, should she take? Her employer, while anxious to retain her service, is equally anxious to avoid running unjustifiable risks.*

A.—With very rare exceptions there is no risk of contagion or infection from a patient suffering from lupus vulgaris. So far as the lupus vulgaris itself is concerned there is no risk whatever, and it is almost true to say that the presence of lupus vulgaris in the skin denies the presence of any active visceral or other lesion which might be a source of infection. Should such active tuberculosis arise elsewhere it is customary for the lupus vulgaris to disappear quickly. However, there are rare exceptions where patients with lupus vulgaris have visceral tuberculosis, and treatment of the lupus should not be undertaken until the patient has been carefully overhauled medically and by *x*-ray examination of the chest to exclude such a possibility. If that has been done in this instance and all is satisfactory, there is no reason why the patient should not continue in her employment, and in care of the children, and "live in." Most patients suffering from lupus vulgaris are best treated in properly equipped hospital departments, by daily treatment as out-patients while continuing their normal vocations. Such circumstances probably play a part in the response to treatment and in recovery.

Chronic Prostatitis

Q.—*A patient has chronic prostatitis due to Staph. albus and a mildly haemolytic streptococcus. Sulphadiazine and penicillin have been used without appreciable effect. He has had severe "rheumatic" pains in most parts of his body for years. Would an autogenous vaccine help, or would shock therapy be likely to cure?*

A.—To treat any lesion by vaccines without knowing its pathological anatomy is unsound. The query gives no description of the rectal and bimanual examination of the prostate. Even when this has been done the case has not been completely investigated until a posterior urethroscopy has been carried out. It is only by this means that dilated ducts, perhaps exuding pus, can be recognized. An *x*-ray film to exclude prostatic calculi is also necessary. If these special examinations are negative it may be reasonable to try vaccine treatment. Shock therapy is not likely to be useful. If gross disease, recognized by the methods mentioned above, is found, then probably surgical treatment through the posterior urethra, laying open the ducts widely by a diathermy knife, may lead to cure.

Thiouracil for Graves's Disease

Q.—*What is the mode of action of thiouracil in Graves's disease? What are the drawbacks? Is it possible to use it in general practice, and if so in what dosage, and what precautions are necessary? Is there any concise literature on the subject?*

A.—Thiouracil acts by interfering with the production of thyroxine in the thyroid gland. By means of thiouracil thyrotoxicosis can be controlled, but unfortunately about one in every ten patients shows signs of sensitivity to the drug and treatment has to be discontinued. Such sensitivity usually occurs during the first eight weeks of treatment, and infrequently later when maintenance doses of the order of 100 mg. to 50 mg. daily are being used. The most dangerous manifestation of sensitivity is agranulocytosis. Treatment with thiouracil is justifiable only when the patient can be kept under close observation. She should be in hospital for the first month, and thereafter seen at intervals of not more than one month. In hospital, treatment can be controlled by estimation of the B.M.R., and sensitivity detected by counting the white blood cells. After discharge, counts of the white blood cells should be made at monthly intervals. The duration of treatment is six months to one year. A concise account of the treatment and its drawbacks is given by H. P. Himsworth (*Proc. roy. Soc. Med.*, 1944, **37**, 693).

Pneumoperitoneum for Early Apical Tuberculosis

Q.—*On page 520 of the* Journal *of Oct. 13 a question is headed "Pneumoperitoneum and Pregnancy." Presuming the "apical lesion" refers to the chest, is pneumoperitoneum a recognized treatment for this, or is this a slip for pneumothorax?*

A.—Pneumoperitoneum is often a very useful measure in the treatment of early apical tuberculosis, especially when combined with paralysis of the hemidiaphragm. In these circumstances very considerable relaxation of the lung can be obtained, which affects all parts, including the apex. Obviously the treatment would have no effect in cases of chronic, cavitated, fibroid, apical disease.

Keeping Properties of Penicillin

Q.—*How long does penicillin retain 75% of its potency (a) once dissolved for intramuscular use or for use as eye-drops; (b) when made up in the form of pastilles for oral medication in Vincent's infection? As the keeping property varies with temperature, I should like a figure for room temperature and for 5° C.*

A.—A precise answer to this question cannot be given, if only because stability depends on purity. The rapid loss of potency in solution which characterized the cruder penicillin of early days does not occur with the more refined present-day product, but different makes and batches still vary in their content of impurities. Some idea of the stability in solution of reasonably good penicillin may be gained from the observations of W. M. M. Kirby (*J. Amer. med. Ass.*, 1944, **125**, 628), who kept weak solutions at incubator and room temperature and could detect no deteriorations until after 4 and 7 days, respectively. J. S. Gotts and A. M. Glazer (*War Med.*, 1945, **7**, 168) found that solutions and creams lost the whole of their activity in about one month at either incubator or "room" temperature (this, being in summer in Florida, averaged 28° C.), but lost practically none of it in the refrigerator (2° C.) in 60 days. In preparations other than simple solutions stability might be affected by the vehicle, but the bases used both for creams and for pastilles are understood to have no deleterious effect. It need perhaps hardly be added that one cause of very rapid loss of potency in any fluid preparation of penicillin is bacterial contamination; frequently used solutions such as eye-drops are particularly liable to this.

Inheritance of Diaphysial Aclasis

Q.—*What advice should I give a female patient aged 23 about the advisability of marriage? There is a family history of multiple congenital osteochondromata. Her grandmother was affected; her father was free from it; but his six brothers developed bony growths at 2½ years of age. The patient herself is free, but her brother developed the complaint in infancy, and now his son (the patient's nephew) has developed growths at the age of 2½ years. All the bony growths appear near the epiphysis of long bones or on the spine. Is the aetiology known? And is any preventive treatment by drugs—e.g., calcium—of any use?*

A.—The condition is probably diaphysial aclasis (multiple exostoses). It is inherited as a dominant, but in the heterozygous state, particularly in females, the exostoses may be so small or so few that they are overlooked, and sometimes there may be none at all. In view of the fact that the patient's father was apparently free and yet transmitted the condition, the patient may also be capable of transmitting it. It is, however, more likely that all her children and descendants will be normal. If she does decide to get married it would be advisable, before taking this step, to have *x*-ray films of all her long bones and spine taken. It is an inherited developmental defect of bone, but the exact nature of it is unknown. No treatment with the drugs which have been tried so far has had any effect.

"Leucopenic Index" in Allergy

Q.—*Is there a reliable quantitative test of protein sensitivity in allergic conditions? In Bigger's "Medical Bacteriology" (4th edition, p. 265) mention is made of a test called "leucopenic index." How is this test performed and what is its clinical value?*

A.—The "leucopenic index" was suggested by Vaugham (1932). The principle of the test is the same as that of the haemoclasic crisis test of liver function (Widal), the occurrence of a leucopenia after the ingestion of food instead of the usual digestive leucocytosis. Vaughan found that the drop occurred after a patient partook of the food to which he was sensitive. Two leucocyte counts thirty minutes apart are made on a patient who has fasted for at least six hours. One and a half hours after the ingestion of the suspected food another leucocyte determination is made. If the number of leucocytes after ingestion is 1,000 lower than before the result is considered positive, but all the work should be done by a single technician, using the same apparatus, and the patient must have been at rest and not mentally upset. Only one food can be tested on one day, and repetition of the test often yields different results. The test has received both support and criticism. According to many observers, sometimes a rise comes instead of a fall. Even Vaughan considers that it cannot be regarded as a diagnostic procedure in allergy. As yet it is certainly not reliable, and has been used only in food sensitivity and not in the more common inhalant sensitizations.

Air Embolism in Pregnancy

Q.—*Recently a case was reported in which death occurred in a pregnant woman due to air embolism stated to be caused through blowing during or shortly after intercourse. It was said that this condition, unknown to the laity, was only little known to medical men. How exactly is it brought about? Why is there a greater risk of air embolism during pregnancy? Is air embolism possible by blowing up the vagina?*

A.—Fatal air embolism (the air gaining entrance via endometrial vessels) has been recorded in non-pregnant women when air is forced directly into the uterus—as in tubal insufflation. The chance of this, small at any time, is increased just before menstruation when the endometrial vessels are dilated. During pregnancy, when the vessels of the decidua are widely dilated and their walls fragile, the risk of air embolism is much greater. If the cervix is slightly open embolism can occur even if the air is forced only into the vagina. It is more likely in multiparous women and in late, rather than early, pregnancy. Although air might gain entrance through a damaged vessel in the vagina or cervix, the usual route is for it to travel through the cervix, outside the membranes, up to placental site, where it enters one or more of the maternal sinuses. At least four cases[1-4] of fatal air embolism following the vaginal insufflation of antiseptic powder during pregnancy are recorded, and I know of one other, not published as yet. It is stated that it requires 500 c.cm. of air to enter the blood stream to produce death; and Breyfogle estimates the capacity of the distended vagina during pregnancy to be in the region of 1,150 c.cm. If the maximum amount of air which can be expired is put at 3,500 c.cm. after a full inspiration, and at 2,000 c.cm. after a normal inspiration, it is clear that with a single expiration an individual could blow enough air into the vagina to fill it to capacity and also to cause fatal embolism via the uterus. There is, therefore, little doubt that the forcible blowing of air into the vagina, and particularly if the introitus were obstructed at the same time, could result in fatal embolism. The fact that post-mortem examination may not reveal the site of entry of the air or any separation of the membranes is not necessarily of significance, since the findings in this respect were negative in at least two of the recorded cases of death following insufflation.

It remains to be added that air embolism may occur during intra-uterine manipulations in labour, and is most common immediately after delivery is complete, when air may be sucked into the uterus by intermittent pressure applied to the fundus. Its causation is dependent on the same factors: (1) entrance of air into the vagina under pressure, (2) an open cervix, (3) the widely dilated venous sinuses of the placental site.

Purifying Water Supplies

Q.—*Is chlorination of water effective—that is, does it destroy germs, such as Bact. coli? Is there any other efficient means of purifying a city's water?*

A.—Chlorination is the most widely used method of sterilization of water. It is employed as the final or sometimes as the only stage in the purification of surface supplies, and is often the only treatment required for well supplies where the water is bright and clear. Chlorine is a germicide and obeys the laws of disinfectant action. In waterworks practice the aim is to destroy all intestinal organisms; for if all the normal inhabitants of the human and animal intestine, such as *Bact. coli*, are destroyed, then it can confidently be assumed that all pathogenic intestinal organisms have also been killed off. A water is considered safe to drink if *Bact. coli* is absent from 100-ml. samples. Chlorine may be added to water in several ways, but there must be adequate time for contact between the chlorine and the water for the disinfectant action to be completed before the water passes to the consumer. In this way the dose of chlorine applied may be so small that no taste of it can be detected by the users.

Ozone is another efficient "finishing process" in the purification of water, and, although more popular on the Continent than in this country, it may become more widely adopted here as cheaper methods for its production are devised. This allotropic form of oxygen has some advantages over chlorine. In addition to the production of a clear and sparkling water, it is capable of removing certain earthy or musty tastes and odours and of reducing colour. Ozone completes its beneficial effect within a few minutes and decomposes into oxygen, so that it may be said that no "foreign" substance is present in the water.

Enemas in Diphtheria

Q.—*For how long should enemata be given to a moderately severe case of diphtheria? What is the safest laxative to give when enemata are discontinued?*

A.—In diphtheria of such severity as to introduce the possibility of toxic myocarditis bowel action is best maintained by small enemata on alternate days throughout the whole period of strict recumbency. Once the child is sitting up in bed aperients may safely be used, but they are often not required in young children. A suitable one in diphtheria at all ages is an equal mixture of liquid paraffin and liquid extract of cascara in appropriate amount.

INCOME TAX

Appointment—Expenses: "Living In"

A. B. receives a salary of £350 a year as a demonstrator. (*a*) What deduction can he claim for subscriptions for professional literature, or to professional societies, renewal of instruments, etc. (*b*) How will he be affected if (i) he "becomes resident with the cost of residence deducted at source," or (ii) "takes a post with residential emoluments"?

⁂ (*a*) No deduction can be claimed unless membership of the societies is a condition of the appointment, or, in the case of instruments, he is required to supply his own. If he is not debarred by that condition reasonable out-of-pocket expenses can be claimed provided that they are not of a capital nature. (*b*) (i) If he is entitled to a specified salary (of £*x*) but being resident is liable to have a deduction (£*y*) made therefrom in respect of board and lodging, he is liable to tax on the full amount—i.e., £*x*. On the other hand, if the terms of the engagement are that he shall receive a specified sum (£*x*—£*y*) and in addition have the advantage of free board and lodging, then his liability is on the actual cash payment due (i.e., £*x*—£*y*).

Locumtenent—Expenses

N. H. has been informed that commission paid on his salary as a locumtenent cannot be deducted as expenses under Schedule E.

⁂ The statement is legally correct but requires amplification. It is the accepted practice to assess a locumtenent—meaning by that a medical man who practises his profession by taking comparatively short-term engagements—not under Schedule E as if he holds a series of appointments each one of which is a separate subject of assessment, but under Schedule D as a man exercising his profession in a special way. If, therefore, N. H. has held a number of locumtenencies or in the natural course of events will do so, he should claim that under the recognized practice of the Inland Revenue Department he should be assessed under Schedule D (in which case the commissions payable can be deducted as expenses) and that the Schedule E assessment should be discharged.

LETTERS, NOTES, ETC.

Use of Liver Extracts

In the JOURNAL *of Oct. 6 we published a question and answer on the use of liver extracts. The answer was criticized in the* JOURNAL *of Nov. 17 (p. 714) by Dr. H. M. Walker. Our adviser replies as follows:*

It was made clear in the answer to which Dr. H. M. Walker demurs that liver extract cannot be expected to cure aplastic anaemia or thrombocytopenic purpura. It might have been added that, though the Order made by the Minister of Health on July 19, 1945, permits injectable liver extracts to be used without any restriction as to the conditions to be treated, it is still a breach of the regulations to use oral extracts of liver for any conditions except pernicious or other megalocytic anaemias. Moreover, it was apparent from the context that the reference was to anaemias of a grave prognosis, and the writer would strongly discourage the injection or ingestion of liver in the simple form of hypochromic anaemia which is so common in women in this country. The rule might therefore be amended to read, "No patient with a blood disorder should be allowed to die without being given the opportunity of responding to liver therapy," and the writer has no hesitation in reaffirming it in that form.

It seems probable that Dr. H. M. Walker has had little experience of treating patients with severe blood disorders such as aplastic anaemia or acute leukaemia. In their extremity the relatives turn for help in every direction, and sooner or later they discover that a patient with a severe anaemia has made a miraculous recovery on treatment with liver. It may be disastrous if they make such a discovery after their own patient has died without benefit of liver therapy. It is idle to try to persuade them that this is an entirely different type of blood disorder. In the first place, they ask, may we not be wrong? And in the second place, can it possibly do any harm? We may indeed be wrong. The writer has seen patients recover completely on treatment with liver when they had been diagnosed as suffering from carcinoma of the stomach with pyloric deformity; aplastic anaemia; purpura haemorrhagica; and cirrhosis of the liver. Liver is undoubtedly often misused, and that is a bad thing in these times of scarcity. Before the war more batches of liver extract were sold than there were patients with pernicious anaemia on whom to test them. Nevertheless, the great volume of misused material goes to people who are not anaemic at all, and who sometimes quite frankly take it as a pick-me-up. The amount that will be wasted in parenteral treatment of aplastic anaemia, purpura haemorrhagica, and leukaemia is a mere trickle in comparison.

Dr. H. M. Walker further states that purified and crude extracts of liver are equally reliable, and that they are submitted to exactly the same type of test. This may be true of some particular brands, but it is certainly not generally true. There is no compulsion on British manufacturers to submit liver extracts to clinical trial and to record their potency in units, as is the rule in Canada and the United States. It is well known to practising haematologists that some British manufacturers have put batches of liver extract on the market without clinical trial during the war, and that the commonest cause of relapse in treated cases of pernicious anaemia has been an inactive preparation of liver. It is also a matter of experience that the refined extracts have been more reliable than the crude.

Finally, Dr. H. M. Walker misquotes the answer in regard to the use of proteolysed extract of liver. Injection of liver extract was recommended as the treatment of choice for pernicious anaemia, but it was pointed out that refractory cases which fail to respond to treatment by injection will often respond to proteolysed extract of liver by mouth. Evidence of the decisive superiority of proteolysed extract by mouth in refractory anaemia of the pernicious type can be found in the paper by Davis and Davidson (*Quart. J. Med.*, 1944, **13**, 53). In the experience of the present writer fluid extract of liver (*B.P.*) is as effective as proteolysed extract in these uncommon refractory pernicious anaemias. The explanation of the superiority of oral over parenteral treatment in these particular instances is obscure. It may be mass action of the extract, or it may be the presence of synergic factors which are not available in sufficient quantity in the parenteral preparations. As Dr. H. M. Walker has misconstrued the previous answer, he may rest assured that the writer is well aware of the fact that in the average case of pernicious anaemia liver extract is probably 40 to 60 times as active by injection as by mouth. In refractory cases of pernicious anaemia, however, there is a diminution or reversal of this ratio, and in refractory cases, therefore, oral extract of liver may be superior to intramuscular extract of liver, however complex and however carefully assayed.

"The Frozen Pelvis"

Lieut.-Col. F. R. W. K. **ALLEN** writes from the Indian Military Hospital, Poona: The reviewer of *Surgical Errors and Safeguards* in your issue of July 7, 1945 (p. 16) should look up O'Meara's *Medical Guide for India* and turn to Section VI, 7, "Gynaecology," by V. B. Green-Armytage. "The frozen pelvis" appears in my edition at page 722.

Humanitarianism and the European Situation

Mr. J. W. **NIEMANN**, chairman of the Reception Committee for Young People from Occupied Countries, writes from 35, Eaton Square, London, S.W.1: I have been advised by one or two doctors that a letter appeared in your *Journal* on Sept. 29, written by a doctor serving in U.N.R.R.A., who asked that an organization be set up to enable children from the Continent to come to this country for a recuperative holiday of twelve months or so. I would like to draw attention to the work of the Reception Committee, Y.P.O.C. This organization has been in existence since 1942 and has been working in close collaboration with the British and Dutch Governments. Up to date nearly 6,000 Dutch children have been accommodated in this country, and all of them have been in camps for two months, 5,000 of whom have also been in private hospitality homes for a further eight weeks. These children have been distributed with great success into private homes in Scotland, the Midlands, and Wales, and we are now busy on plans to send about a thousand children to the southern districts of England, including Kent, Surrey, and Sussex. These children are welcomed as guests in the homes of these British people, and from all sides we have been encouraged by excellent reports. The Reception Committee is run on voluntary subscriptions, and the administrative work of the headquarters is carried out locally by branch reception committees, all of whom work in an honorary capacity. The organization is international, and we are hoping to welcome children from Norway, France, Czechoslovakia, and Greece.

SUPPLEMENT TO THE
BRITISH MEDICAL JOURNAL

LONDON SATURDAY DECEMBER 1 1945

HEARD AT HEADQUARTERS

The Profession in the Making

Medical students from all, or nearly all, the schools of Great Britain and Ireland held their annual meeting at B.M.A. House during the last week-end of October. The medical profession in the shaping promises well. The students are refreshingly free from the inhibitions of their elders, and do not recognize the need for being excessively polite to one another when they differ. Disagreements were talked out frankly, which is all to the good. It was also interesting, at the beginning of the conference, to hear a grave protest from a Cambridge delegate at the alleged facetiousness of the reports and news letters circulated to the schools from the headquarters of the B.M.S.A. Was this a national body or was it not? If it was a national body such facetiousness was out of place. The retiring president, Mr. John Rich, of London, nobly took the blame. He said that his predecessor had sent out most serious and succinct letters, which had been posted up on notice boards and not read, and to his mind some element of facetiousness was necessary in order, so to speak, to cross the student threshold.

Student Opinion

The British Medical Students' Association was established three years ago and has already done some excellent work. Such a body suffers inevitably from some lack of continuity. As soon as a member becomes exceptionally useful and reaches high office he is likely to have come to the end of his undergraduate career, and, as a young doctor, he is no longer eligible for membership, and probably would not be interested in student affairs if he were. The association got out a useful report on the National Health Service, but further work on that is " hanging fire " while the Government's proposals are still unannounced. Another report is on the Goodenough recommendations, and yet another on student health. The B.M.S.A. is now hard at work through its new secretary, Michael Honey of Cambridge, collecting material on the cost of medical education. How much does it cost to qualify as a doctor, and to what extent is financial help available by means of scholarships, grants, or loans from the State, from local authorities, from universities and medical schools, and from private trusts? And yet further, how many young men and women who might be expected to make good doctors are prevented from pursuing the profession solely because they cannot afford the money for training?

Cost of Medical Education

This cost of medical education is a question on which the students feel deeply. Some investigations made at Newcastle were cited, from which it appeared that the cost of six years' medical education worked out for the average student at £1,070 if he lived at home, and £1,380 if he was in lodgings, to which amounts should be added the loss of early earnings which would have come to him had he followed some occupation that demanded less in the way of training. But there is a great difference in these costs as between London and the Provinces and as between the Provinces and Scotland ; so much so that it has been found impossible to draft a single questionary which would apply to all medical schools. One student from Manchester argued that as the profession is likely to come under the jurisdiction of the Government, the State should bear the whole cost of medical education—rather a breathtaking proposition. The conference did pass a resolution urging the Ministry of Health, the voluntary hospitals, and other authorities concerned to adopt for all recently qualified persons a uniform commencing salary scale ranging, according to the grading of posts, from £200 to £400 a year, with full residential emoluments, and also that during the pre-registration period of internship payment at the rate of £100 a year, again with residential emoluments, should be made. Another question on which the students had ideas was the general education programme. One motion from Birmingham—not put to the meeting—was that the first year at the university should be given up to purely medical education, imparted in a general way, so as to get the general view before the particular. Someone else wanted wards to be opened to students in the afternoons during vacations and classes to be held at such times by registrars.

Student Health

A good deal of concern was expressed at the students' conference about the health of students in general—not medical students only, but all at the universities. They are at a critical age, not usually well-to-do, and they are not insured persons. Their lodgings very often lack much in home comfort, and college canteens are said to be in some cases only in the " C " category, which means that their allowance of essential foods is very small. Mass radiography is being carried out among students ; at Liverpool, out of 1,465 students at the university, 1,245 have been examined, and at Belfast 623. Health services for students, including a medical examination on entrance and re-examination at regular intervals, were pressed. The schools are also being urged to organize local insurance schemes.

Full House

A Council meeting in which every one of the sixty-three members attended may well be a record in B.M.A. annals. Whether it was the prospect of meeting the new Minister of Health or the fact that an unusual number of important matters were down for decision, not a seat was vacant when the Council met on Nov. 7. The usual item " Apologies for Absence " had been pessimistically placed on the agenda, but none was forthcoming. It is interesting to estimate the mileage travelled in connexion with such a Council meeting. Only about one-third of the members live in London or within fifty miles of it. Ten members (from Scotland and Northern Ireland) travelled over 300 miles in order to attend ; five (from the North of England) travelled between 200 and 300 miles ; twenty-two (from the Midlands and South Yorkshire, the West and South-West of England, and Wales) travelled between 100 and 200 miles, and four others between 50 and 100. Although not technically the first meeting of the new session, it was a meeting of new beginnings. Dr. James Fenton was welcomed on his first appearance as chairman of the Public Health Committee, and Dr. J. A. Pridham as chairman of the Organization Committee. The new Northern Ireland Committee presented its first report, and a report was forthcoming from the Welsh Committee, which has not met during the war, though its Contract Practice Subcommittee has been active.

The Minister of Health

It was interesting to hear the reactions of various members of Council after meeting the new Minister of Health. One highly critical member described him as " obviously clever and charming, with the cherubic outlook and manner of a boy." There is something disarming about the way in which the new Minister confesses his ignorance and his willingness to learn. He attended a meeting of medical men the day after he had visited the Council, and said that he had been primed by his Department as to what he should say on the occasion, but it would be too embarrassing for him to use the documents prepared for him, because it would be a pretence to knowledge which he did not himself possess: very unlike some former Ministers—not Ministers of Health alone—who have come along and read speeches in which they assumed omniscience. At the same time, behind this disarming front there is probably a very combative spirit. The Welsh Aneurin from whom Mr. Bevan takes his name was both a bard and a warrior.

THE BUYING AND SELLING OF MEDICAL PRACTICES

A LAYMAN LOOKS AT THE PROBLEM

The Minister of Health has not yet announced the intentions of H.M. Government about the buying and selling of medical practices. Let me assume, for the purpose of this article, that the Government decides to prohibit the custom. What would this mean? First of all, why have practices been bought and sold? Let us try to examine this question without prejudice.

Doctors, in the main, are not wealthy. Generally speaking, they become comfortably off only after many years of hard work. Their only asset, in a business sense, is what is known as goodwill, and this is what is bought or sold when a practice changes hands. Goodwill is an expression of the success or failure of an individual or business to satisfy clients or customers. If it has a high financial value it indicates success; if low it proves failure.

When a shop changes hands but the name on the front remains the same it is clear that the business was a success and the late owner had earned the goodwill of his customers. The purchase price would, therefore, include an amount for goodwill, which might even be more than the value of the premises and stock. The buyer of the goodwill would, in return for his money, get the opportunity of trading at once with a number of satisfied customers, who would remain his customers only if he continued to prove himself worthy of their goodwill by satisfying them. He would also receive an assurance that the seller of the business would not start again round the corner and take all the customers back. This is a well-understood procedure, and not only does no one object to it in business life, but everyone agrees that it is a simple and straightforward way of handing on, or of acquiring, a connexion which has taken a lot of time and energy (or would do so) to build up. That this goodwill has a financial value is beyond dispute.

Now what is wrong with the buying and selling of practices —i.e., of medical goodwill? Nobody raises a protest when a would-be shopkeeper buys the goodwill of an existing shopkeeper, simply because there is nothing wrong about the transaction. Solicitors, architects, and accountants are never attacked because their partnership agreements are based on goodwill. Why, then, is the medical profession singled out for attack?

Apparently in the minds of some people there is a difference between the medical profession and other vocations. Because doctors apply their specialized skill to healing the sick and because sickness and suffering go together doctors are supposed to take a more unworldly view of their work than other people do of theirs. There is, of course, nothing horrible about the buying and selling of practices. A doctor, having given satisfaction over a number of years to a number of patients, can reasonably expect that, given the same care and attention, those patients will continue to come to him for a further period of years. This assurance gives him an expectation of income which an accountant can translate into a capital value.

Now supposing a doctor finds that the place he is in does not suit his wife or he wants to leave it for some other reason, or wishes to retire, he can, under the present method, select another doctor and introduce him to his patients, recommend him, and hand the practice over in return for a payment calculated on the capital value of anticipated income over an agreed period. With this money he can make an offer for a practice in an area that suits him better or add to his savings on retirement. If the doctor who has taken over the practice fails to satisfy the patients they leave him and it is his own fault. If the one moving to the new practice similarly fails it is his own fault. In other words, the patient is under no obligation to either doctor. So far as the patients are concerned they may get a better or not so good a doctor, *but they get one who wants to be there* instead of retaining one who wants to go. Nobody, therefore, is penalized. Doctors have their freedom and the patients have theirs. There is nothing sordid about the matter. The fact that it is a straightforward business deal does not make it unethical.

The other objection to the buying or selling of practices is that only the children of the rich can become doctors. That can most easily be remedied by granting more scholarships. It is the long training which costs the money.

As to the buying of a practice, there are many ways in which the poorest of qualified doctors can acquire the necessary funds without crippling themselves. There is a lot of uninformed talk about young doctors "mortgaging themselves to insurance companies" as though they were the only people who ever used the facilities offered by financing institutions. Here is a typical example of how a newly qualified doctor can buy a practice.

Dr. X, who has no capital, wishes to buy a practice. He need not be deterred, because there are ways and means by which this can be done. He can approach, say, an insurance company and obtain a loan on the security of his anticipated earnings—i.e., on the goodwill of the practice. The company would also ask that as additional security he should insure his life for an amount sufficient to cover his indebtedness. If he is wise he will, of course, have already insured his life. He could arrange to repay the loan together with the interest by instalments, and on a loan of £1,000 the yearly payment would probably be about £125, so that he need suffer no more hardship than anyone else starting a career on his own. All the time he would be gaining possession of a capital asset the value of which he could increase by his own efforts. It is possible that in some cases there would be no need to approach a business firm. In the case of a doctor who is offered a share in a partnership, for example, it might well happen that the price asked for the goodwill might be paid on a "pay-as-you-earn" arrangement acceptable to the senior partner.

It is apparent, therefore, that the objection is ideological. It has nothing to do with ethics, justice, morality, or whatever you care to call it. It is simply that some people believe that everybody and everything should be subservient to the State and that free transactions between free individuals are wrong anyhow. As the medical profession will be required to take a leading part in making the social security plans work they are first on the list of individuals to be controlled, but only the first. All the others must follow. What will be the consequence to patients of the prohibition?

Doctors will first of all be unable to move without sacrificing their goodwill. This will not tend to make them happy in their work. As there will be no "free market" in practices doctors wishing to find employment will have to apply to a central registry and go where the Ministry of Health says there is a vacancy. It will, in effect, become civil direction in peacetime, though it will not be called that. This will not suit most doctors, and those it suits will not be the best doctors. Far from getting a better service as the result of depriving doctors of their freedom the public will get a worse one. Without for one moment criticizing the medical services of the Forces it is suggested that both Service doctors and Service patients in the great majority of cases prefer private practice and private treatment. It is the physical facilities available in the Forces, not the discipline and methods of organization, which are appreciated by doctor and patient alike.

When the medical practitioner is the sole arbiter of whether or not some benefit shall be paid or prolonged and, by reason of his loss of freedom, is a servant of H.M. Treasury, the public may regret the departure of the old-fashioned G.P. who bought his practice and from the stronghold of his independent position could stand up as advocate for their rights as well as his own. The fact that compensation for loss of goodwill may be paid in the form of a retiring pension does not affect the major issue so far as the public are concerned, nor so far as newly qualified or unplaced doctors are concerned. The public will almost immediately feel the disadvantages of a State service in which the doctor represents the Treasury against the patient (see Beveridge report and report of Government actuary on Social Insurance), and the doctors will at once find themselves immobilized or directed.

At the annual meeting of the St. Helens (National Health) Insurance Committee Dr. D. Campbell, M.R.C.P., was appointed chairman of the committee for the eleventh consecutive year.

GENERAL MEDICAL COUNCIL

PRESIDENT'S ADDRESS

At the opening of the one hundred and sixty-sixth session of the General Council for Medical Education and Registration on Nov. 27 the President, Sir HERBERT EASON, gave an address.

He recorded with the deepest regret the death of Mr. N. Bishop Harman, which followed so shortly on his retirement from the Council. "I can add little to what I said on that occasion about Mr. Bishop Harman in May, with regard both to his valuable services to the Council, and to the affection with which he was regarded by his colleagues. His death brings home to us the fact that we have lost for ever a good brain and a kind heart." The President also recorded regret at the retirement in June of Prof. W. J. Wilson, who had represented the Queen's University of Belfast since 1941, and has been succeeded by Dr. W. W. D. Thomson, professor of medicine in the University. "We also welcomed at the session in May Dr. N. E. Waterfield, who is a direct representative elected by the Council under its emergency powers to fill the vacancy caused by the retirement of Mr. Bishop Harman. We have already experienced some indication of Dr. Waterfield's value to the Council through his wide knowledge of the principles of practice which ought to govern the ethical conduct of the members of our profession. We further have to welcome on this occasion Prof. R. M. F. Picken, who fills the vacancy caused by the lamented death of Mr. Sheen. Prof. Picken's experience as the medical officer of health of a great Welsh city, and in the chair of preventive medicine in the Welsh National School of Medicine, together with his presidency of the Society of Medical Officers of Health, will render his advice of great value to the Council in the revision now in progress of the Rules as to courses of study and examinations for diplomas in public health. Finally, we have to congratulate Lord Hacking on his elevation to the Peerage on the occasion of the dissolution of Parliament."

The Education and Examination Committees would be considering the general reports of the inspectors in medicine and in midwifery, Prof. J. A. Nixon and Sir William Fletcher Shaw, as an inspection of all final examinations in these subjects had now been completed. Owing to the death of Mr. Harold Collinson it would not be possible for the Council to have a general report on the examinations in surgery, but Prof. Nixon had prepared for the confidential information of the Council a memorandum on the reports of Mr. Collinson on the several qualifying examinations in surgery at which he attended. The Curriculum Committee were making good progress with their task, and matters had now progressed so far that it would be advantageous at this session for the three committees dealing with pre-clinical studies, clinical studies, and social medicine and public health to meet jointly and pool their ideas, and if possible cement them into a consecutive whole.

Consolidation and Amendment of Medical Acts

The special committee of the Council on consolidation and amendment of the Medical Acts, appointed a year ago, would be considering at this session how far any future proposals by the Government as to a National Health Service might necessarily involve amendments of the Medical Acts. If, for example, the Government were to accept the recommendation of the Interdepartmental Committee on Medical Schools in favour of a requirement that men and women who had passed their final examinations in medicine, surgery, and midwifery should be required to hold certain house appointments before they could be registered in the *Medical Register*, substantial amendments of the Medical Acts would be required to meet the new situation.

But the Council and the public are, I believe, as much interested in the consolidation as in the amendment of the Acts. Since the principal Act was passed in 1858, Parliament has added to the Statute Book no fewer than twenty or thirty other Acts which directly affect the constitution and functions of the Council and of the constituent licensing bodies. We do our best to assist ourselves to find the way through this mass of legislation by means of the book containing reprints of the more important Acts, or parts of them, which members have in front of them. But their problem is reminiscent of a passage "Concerning the Service of the Church" in the Introduction to the Book of Common Prayer: "Moreover the number and hardness of the Rules called the *Pie*, and the manifold changings of the Service, was the cause, that to turn the Book only was so hard and intricate a matter, that many times there was more business to find out what should be read, than to read it when it was found out."

It will therefore be for the Special Committee also to consider on what lines any proposals for the consolidation and amendment of the Acts could best be drawn up so as to preserve what is valuable, to dispense with what is obsolete, and to introduce what the experience of nearly ninety years has shown to be desirable, or the future, so far as can be foreseen, will require. This is a heavy task, but the time which it takes will have been well spent if it enables the Council to be ready with suggestions for the consideration of the Government and their expert advisers should they find themselves disposed not only to amend what must be amended, but to consolidate and amend what must be so treated if a single and intelligible Medical Act is to be made available for the public good.

MEDICAL WAR RELIEF FUND

FIFTH ANNUAL REPORT

1. This report covers the twelve months from Sept. 1, 1944, to August 31, 1945. The year's work shows a considerable increase on that of previous years as regards both the number of applications received and the total amount spent in awards. This increase was particularly marked towards the end of the year, the amount voted in gifts and loans in August being more than three times the average of the earlier months..

2. The number of awards made during the year is fifty-six. Approximately one-half of the beneficiaries were medical officers in the Services or ex-officers who had relinquished their commissions through ill-health or had been released under the reallocation of man-power scheme. The number of appeals from men in the latter category has been growing rapidly. Some of the returning Service doctors need substantial help while they are rebuilding seriously depleted practices. Others are unable to resume their former activities owing to disablement resulting from wounds and require assistance in establishing themselves in new forms of professional work.

3. The other cases dealt with during the year are similar to those which have been described in earlier reports. They include seven in which assistance towards the maintenance and education of children was given to widows of medical officers killed on active service, one of whom had been awarded posthumously a very high decoration for great gallantry in the action in which he lost his life.

4. The audited statement of account for the twelve months is appended to this report. It will be seen that the amount spent in awards is about three times the amount of the new income from donations during the year. The Committee of the Fund expects that, as demobilization proceeds during the next year, far heavier demands will be made on the Fund's resources than ever before. It has therefore decided to launch a fresh appeal for subscriptions in order that the balance remaining in the Fund may be very substantially reinforced.

5. The work of the Prisoners-of-war Subcommittee during the year has been limited owing to difficulties in the transport of books to the prison camps and the eventual release of the prisoners. Fifteen applications for books were received and thirty-five books ordered for dispatch to the camps.

6. The Fund has suffered a heavy loss in the resignation of Sir Hugh Lett from the Committee of the Fund and the Distribution Subcommittee on account of pressure of other duties. Sir Hugh had been chairman of the subcommittee since the inauguration of the Fund and had earned boundless admiration by his intense devotion to the work, his unexampled thoroughness in presenting the applications, and his most wise, tactful, and altogether efficient conduct of the proceedings. The committee records with deep gratitude its appreciation of his magnificent service to the Fund.

7. The committee once again wishes to express grateful thanks for the invaluable help received from the Royal Medical Benevolent Fund; for the continued assistance of the British

Medical Association in providing accommodation for meetings and in other ways; for the most helpful co-operation given by the Education Books Section of the Red Cross and St. John War Organization; for the generous services of Messrs. Price, Waterhouse and Co. as honorary auditors; and for the admirable way in which the genial, tactful, and efficient Honorary Secretary of the Distribution Subcommittee, Mr. E. C. Pennefather, has carried out his increasingly arduous duties.

APPENDIX

Statement of Accounts for the Twelve Months ended August 31, 1945

1. *For Relief of Financial Distress*

		£ s. d.	£ s. d.
To Balance brought forward:			
£7,000 3% National Savings Bonds, 1955/65		7,000 0 0

PANEL CONFERENCE DINNER

A function suspended since 1938 was revived at the conclusion of the Panel Conference when the representatives entertained the members of the Insurance Acts Committee at dinner at the Savoy Hotel. Dr. J. A. Brown presided. The springs of serious oratory had apparently been exhausted during the day's conference, and the proposers of the toasts, Dr. E. J. Allen of Derbyshire and Dr. D. L. S. Johnston of Halifax, in giving the health of the Insurance Acts Committee and of the Chairman, amused the company with some clever persiflage and oblique compliment. Dr. Gregg, in replying, claimed for the Committee that it was the best in the British Medical Association; all its members, he said, were experts in the subject, and his position as chairman called for constant vigilance, because if he made any slip he was sure to be detected. Dr. J. A. Brown, who said that this was the third conference but the first dinner over which he had presided, in his turn proposed the health of the B.M.A. secretariat. Dr. Hill responded for his colleagues—Dr. Macrae, Dr. Potter, Dr. Agnes Kelynack, and Mr. Scrivener, the clerk of the Committee, who was responsible to a very large extent for the smoothness of its working. He mentioned that this was probably the last Conference which the retiring Scottish Secretary, Dr. R. W. Craig, would attend in an official capacity, and on behalf of the London staff he tendered to him their warm thanks for his services and their good wishes for his future happiness. Dr. Hill concluded with an appeal for unity in the ranks. He said that if at any point the Chairman of Council and he were compelled to speak in diffident tones it was because of uncertainty as to whether on that point they could command the full support of the profession. To present the case of a united profession was simplicity itself compared with the task of presenting the mixed views of divided cohorts. There were calls for a speech from Dr. Craig, who in a few words spoke of his pride at having served his fellow Scotsmen and at having retained their esteem notwithstanding the highly critical faculty which was developed north of the Border. He considered himself fortunate in having been able to see the profession inside and outside, first as a general practitioner for many years, and then for fifteen years as an administrative officer, and no less fortunate in having served as such an officer under three chiefs—that wonderful veteran Alfred Cox, George Anderson, whose untimely death they still deplored, and Charles Hill, whose courage and personality were making so great an impression both in the profession and in public life generally. At the close of his speech Dr. Craig was given an ovation by the Scottish members present.

Correspondence

Panel Prescriptions and Certificates

Sir,—One of the chief bugbears of the harassed general practitioner, as we all know, is the enormous amount of clerical work imposed upon him, chiefly the continual repetition of prescriptions and panel certificates. Cannot something be done to alleviate this monotonous burden—a definite obstruction stealing our time, which could be employed in far richer fields? The following suggestions may appear ludicrous and quite impracticable, but in the hope of stimulating further constructive criticism here are a few ideas for what they are worth.

Instead of writing out panel certificates, three coloured disks would be supplied: red disk, first certificate—stop work; amber disk, intermediate; green disk, final—resume work. The disks are *stamped* with the doctor's signature and the date, and then handed to the patient. (No disease is to be stated, as this is confidential between the doctor and patient and should be nobody's business.) Another idea would be to let the patient "clock on" the panel, the necessary machines to be installed in the doctor's surgery; anything to remove this evil in our midst. After all we did spend at least five years training to qualify as doctors, but under the present system if we happen to lose or mislay our fountain pens, instantaneously we become practically useless as a panel practitioner.—I am, etc.,

Nottingham. Gordon Tresidder.

Legal Obligations of the Practising Doctor

SIR,—There are, I believe, some 56,000 members of the B.M.A. Yet from all that number there have been, so far, only two letters of protest over the action of the G.M.C. in punishing a doctor for failure to visit a patient. Are we as a profession incapable of any emotion save that of the tempered joy which we may, or may not, exhibit on the safe arrival of our panel cheques? One can even admire the dockers, for they at least show a sense of cohesion and co-operation and a determination to hang together. Doctors, however, as distinct from dockers, seem to wish to hang as individuals.

What is the B.M.A. doing about it? There are some, we know, who will no doubt say: "Nothing, as usual." Let us have the full facts about this case which is causing much mental disquiet among those who think the price of liberty is eternal vigilance.—I am, etc.,

Hove. G. L. DAVIES.

SIR,—Dr. J. V. Mainprise's letter in the *Supplement* of Oct. 27 (p. 96) raises a most important legal point, on which I agree counsel's opinion should be obtained. Like him I am no legal expert, but the matter is one of great importance to us all, and an authoritative answer should be in our hands as soon as possible to the question: "Where no actual or implied contract exists has a doctor any legal obligation to attend a case merely if asked to do so?" I agree that very often he may have an ethical or humanitarian obligation, and where such exists it is unthinkable that he would refuse if it was physically possible for him to attend, but the legal position should nevertheless be clarified, and we look to the B.M.A. to give or obtain guidance on this important point.—I am, etc.,

Southport, Lancs. R. R. M. PORTER.

Duty of the Profession

SIR,—On all sides we are beset by rumours of the Government's plans for a National Health Service, but now one fact has emerged. Although Mr. Bevan has been in office for 3½ months and promises his "plan" next month he has had no discussions or negotiations whatsoever with our representatives. Now many of the rumours are likely to prove empty, but what of the promised "plan"? Does all this mean that Mr. Bevan is "bluffing," or does it mean that he is about to ignore our opinions?

One thing is certain at this time. It is essential that there should be the greatest possible unity in the profession. To this end we must all strive to the utmost, laying aside our differences so as to maintain the high ideals of the medical profession, whether in its present form or in a new one of which so many of us have such high hopes, but oh, such fears. When unity in the profession is mentioned thoughts immediately go back to 1912 and the failure then to "stick together." Without doubt this was due to the bitter competition between doctors which then existed, and which lowered our prestige so seriously in the eyes of the public that they thought it was but for them to raise a finger for the doctors to scramble for their favour. Fortunately now things are very different; almost everywhere among doctors there is developing a fine comradeship—a comradeship, indeed, which soon may be severely tested.

Although so many of us are hoping for a health service in this country second to none, we must obviously be wary of all politicians and their "catch-phrases." Let us not be misled into hasty decisions; if the "plan" is a good one it will bear scrutiny, and in it plainly visible will be many benefits to our patients and an honourable service for ourselves. If we can see this it will be the clear duty of the profession as a whole to accept the Government's proposals. But what if our hopes are unfounded and we are presented with some political window-dressing instead? Then most assuredly must we give an emphatic "No," and Service men, specialists, general practitioners, stand steadfast against blandishments or threats, refusing any part in the scheme until such changes are made as will permit our consciences to say, "It is good," and only then, all together, we can accept it.—I am, etc.,

Bristol. W. H. HAYES.

Association Notices

GROUP OF DERMATOLOGY

Notice is hereby given of the formation by the Council of a Group of Dermatology, which shall be composed of all those members of the Association who are engaged predominantly in the practice of dermatology. Members of the Association who claim to conform to this definition, including those serving with H.M. Forces, are requested to apply to the Secretary, B.M.A. House, Tavistock Square, W.C.1, not later than Jan. 31, 1946, for a form of application for membership of the Group. The first general meeting of the Group will be held at a date to be subsequently announced in the *Supplement*.

CHARLES HILL,
Dec. 1, 1945. *Secretary*.

Meetings of Branches and Divisions

LEIGH DIVISION

A number of activities were resumed during the year, states the report for 1944–5 of the Leigh Division, which was approved at the annual meeting on Oct. 23. Altogether five meetings were held, to two of which all practitioners in the area were invited. Addresses were given by Dr. G. E. Hayward, Dr. R. Hamilton, Mr. F. H. Scotson, Dr. M. L. Thomson, Dr. F. H. Stratton, and Miss E. M. Mills. The annual dinner was held once more. Of the Protection of Practices Scheme the report remarks that it continues to operate with fair success.

NORTH-EAST ESSEX DIVISION

An open meeting of the North-East Essex Division, to which all doctors in the area were invited, was held at the Essex County Hospital, Colchester, on Oct. 3, under the chairmanship of Dr. Frank Guiver. On the proposition of Dr. A. MacQuarrie, seconded by Mr. T. A. Ogilvie, the following proposition was carried without dissent: That this meeting is solidly behind the Negotiating Committee of the British Medical Association appointed to consult with the Government on the proposed National Health Service, and asks them to stand firm on the principles approved by the Annual Representative Meeting of 1944 and the Special Representative Meeting of 1945.

Branch and Division Meetings to be Held

EAST HERTS DIVISION.—At Long's Restaurant, Bishops Stortford, Wednesday, Dec. 12, 8.30 p.m. to 1 a.m., supper dance.

HOLLAND DIVISION.—At the Café Imperia, 44, Market Place, Boston, Thursday, Dec. 6, 9 p.m., demonstration of talkie film by Dr. J. Stanley White: Sex Hormones—Physiology, Diagnosis, and Treatment. A discussion will follow.

SWANSEA DIVISION.—Thursday, Dec. 13, address by Lieut.-Col. C. J. Cellan-Jones.

WAKEFIELD, PONTEFRACT, AND CASTLEFORD DIVISION.—At Clayton Hospital, Wednesday, Dec. 12, 8.15 p.m., Mr. D. H. Russell: Colliery Accidents.

H.M. Forces Appointments

ARMY

Lieut.-Cols. R. McKinlay, O.B.E., and A. E. Richmond, C.B.E., from R.A.M.C., to be Cols.

ROYAL ARMY MEDICAL CORPS

Lieut.-Col. R. McKinlay, O.B.E., has been restored to the establishment.

Major H. A. Ferguson and Major (War Subs. Lieut.-Col.) J. J. O'Dwyer to be Lieut.-Cols.

Capt. I. D. Paterson has been placed on the half-pay list on account of disability.

Capts. T. W. Carrick and A. J. Fulthorpe, holding short-service commissions, have been appointed to permanent commissions.

REGULAR ARMY RESERVE OF OFFICERS

ROYAL ARMY MEDICAL CORPS

The following having exceeded the age limit of liability to recall have ceased to belong to the Reserve of Officers: Lieut.-Col. F. C. Davidson, M.C., and has been granted the honorary rank of Col.; Lieut.-Col. L. F. K. Way, D.S.O., retaining the rank of Lieut.-Col.; War Subs. Lieut.-Cols. J. P. Litt. W. B. Laird. L. G. Bourdillon, D.S.O., D. McVicker, O.B.E., M.C., W. W. MacNaught, and H. C. Todd, and have been granted the honorary rank of Col.; Majors H. H. Mulholland, W. Stewart, P. A. Stewart, W. A. Rankin, T. K. Boney, P. Carney, M.C., and War Subs. Majors R. N. Porritt, H. B. Walker, M.C., W. Moodie, J. A. Binning, O.B.E., J. E. Foley, T. R. Snelling, and A. L. Taylor, and have been granted the honorary rank of Lieut.-Col.; Majors R. J. Clausen, M.C., and W. F. Christie; Capt. W. L. Partridge, M.C., and has been granted the honorary rank of Major; Capt. J. A. Cowan.

Majors D. Pottinger, M.C., and P. G. Russell, having attained the age limit of liability to recall, have ceased to belong to the Reserve of Officers.

War Subs. Majors W. H. Valentine, O.B.E., and H. D. K. Wright, from Supplementary Reserve of Officers, to be War Subs. Majors.

TERRITORIAL ARMY

Royal Army Medical Corps

War Subs. Major E. Shipman to be Major.

War Subs. Capts. F. D. Hindmarsh and R. W. Malim have relinquished their commissions on account of disability, and have been granted the honorary rank of Major.

War Subs. Capts. D. J. A. Alban-Jones and R. T. R. Freshwater to be Capts.

LAND FORCES: EMERGENCY COMMISSIONS

Royal Army Medical Corps

War Subs. Majors W. E. M. Mitchell, M.C., and F. A. Donnolly have relinquished their commissions, and have been granted the honorary rank of Lieut.-Col.

War Subs. Major A. J. Cokkinis has relinquished his commission on account of disability, and has been granted the honorary rank of Lieut.-Col.

War Subs. Capts. H. G. Floyd, I. Gurland, and N. Wren have relinquished their commissions, and have been granted the honorary rank of Major.

War Subs. Capts. A. C. Miller, L. G. Morrison, W. R. H. Mackay, E. D. Portman, J. Sinclair, and B. R. Medlycott have relinquished their commissions on account of disability, and have been granted the honorary rank of Major.

War Subs. Capts. A. B. Unwin, J. Y. Walker, C. G. Gordon-Wilson, W. G. Roberts, S. Shaw, J. O. E. Apthorp, H. G. Farquhar, D. Y. Carter, and M. B. Watson have relinquished their commissions on account of disability, and have been granted the honorary rank of Capt.

War Subs. Capt. A. L. Karstaedt has relinquished his commission, and has been granted the honorary rank of Capt.

Lieuts. J. S. Chapman and E. R. Corbett have relinquished their commissions on account of disability, and have been granted the honorary rank of Lieut.

To be Lieuts.: M. A. Epstein, A. J. M. Reese, W. C. B. Harrison, T. F. Strang, H. W. Webb, S. H. Wong, D. M. Proctor, W. McC. Anderson, G. B. Barker, J. P. D. Bates, R. G. L. Brittain, D. W. Campbell, R. G. Chaytor, I. M. P. Dawson, C. W. Dixon, E. J. Dowling, J. L. Edmondson, W. N. Fitzpatrick, A. E. Gibbs, F. R. C. Johnstone, H. Kaufman, J. D. S. Melville, J. F. O. Mitchell, J. McC. Murdock, J. E. Norman, E. C. W. Parkes, F. C. Place, J. P. R. Rees, R. G. W. Reeves, A. F. Robinson, G. F. G. Siggins, T. P. Smith, D. B. Spanton, J. H. Stirrat, J. E. Stobbs, D. Q. Trounce, W. J. Vickers, W. J. Walkden, N. P. L. Wildy, N. E. Wood, P. B. Wilkinson, and A. W. W. B. Woods.

WOMEN'S FORCES

Employed with the R.A.M.C.

War Subs. Capt. (Miss) W. M. Creak has relinquished her commission on account of disability, and has been granted the honorary rank of Major.

War Subs. Capts. M. Shack and E. A. Thompson have relinquished their commissions and have been granted the honorary rank of Capt.

Kathleen N. Berger has been granted a commission in the rank of Lieut.

ROYAL AIR FORCE

Squad. Ldrs. H. H. S. Brown and H. P. R. Smith have been transferred to the Reserve and called up for Air Force service.

The following Fl. Lieuts. (Temp. Squad. Ldrs.) have been transferred to the Reserve and called up for Air Force service: J. C. Groves, R. M. Hewat, D. T. Lewis, V. A. F. Martin, V. T. Powell, J. B. Ross, J. D. Tonkinson, C. N. Young, L. L. Ingram, J. I. M. Smith, K. C. P. Smith, S. Kent, P. J. Macnamara, and J. E. Dalton.

P. F. King has been appointed to a short-service commission as Flying Officer, and seconded to Charing Cross Hospital.

Reserve of Air Force Officers

Squad. Ldrs. (Temp.) M. Hamlin, D. G. Smith, and R. C. H. Tripp have been granted the rank of War Subs. Squad. Ldr.

Fl. Lieut. (Temp. Squad. Ldr.) V. D. Jones has relinquished his commission on account of medical unfitness for Air Force service, retaining the rank of Squad. Ldr.

Royal Air Force Volunteer Reserve

Fl. Lieut. (Temp. Squad. Ldr.) A. M. G. Campbell has relinquished his commission on account of medical unfitness for Air Force service, retaining the rank of Squad. Ldr.

Fl. Lieut. (Temp. Squad. Ldr.) H. S. Atkinson has resigned his commission, retaining the rank of Squad. Ldr.

Fl. Lieuts. J. McM. Mennell and W. A. Clarke have relinquished their commissions on account of medical unfitness for Air Force service, retaining their rank.

Fl. Lieuts. J. C. MacWilliam, C. Rutter, R. N. Rycroft, M.C., and B. M. Jensen have relinquished their commissions, retaining their rank.

Fl. Lieuts. A. E. M. Stevenson, W. G. Zorab, C. A. Lewis, and W. Boyd have relinquished their commissions on account of medical unfitness for Air Force service.

BIRTHS, MARRIAGES, AND DEATHS

The charge for an insertion under this head is 10s. 6d for 18 words or less. Extra words 3s. 6d. for each six or less. Payment should be forwarded with the notice, authenticated by the name and permanent address of the sender, and should reach the Advertisement Manager not later than first post Monday morning.

BIRTHS

D'Arcy.—On Nov. 10, 1945, at Londonderry, to Hester (*née* Gourley), wife of Major T. M. W. D'Arcy, R.A.M.C., a son.

Williams.—On Nov. 17, 1945, at the Maternity Hospital, Preston, to Nan, wife of Dr. A. Langford Williams, of 49, Frenchwood Avenue, Preston, a second daughter.

MARRIAGE

Hutchinson—Anderson.—On Dec. 1, in London, Alexander Caldwell Hutchinson, B.Sc., A.M.I.Mech.E., to Geraldine Anderson, M.R.C.S., L.R.C.P.

DEATHS

Bank.—On Oct. 29, 1945, Ernest Gilbert Bank, aged 66, of "Cluny," Manor Road, Wallasey, Cheshire.

Spencer.—On Nov. 16, 1945, Edith Mary Spencer, M.R.C.S., D.O.M.S., at Leicester.

RETURN TO PRACTICE

The Central Medical War Committee announces that the following have resumed civilian practice: Dr. Redvers Ironside, F.R.C.P., at 89, Harley Street, W.1; Mr. E. R. Garnett Passe, F.R.C.S., at 32, Devonshire Place, W.1; Mr. A. E. Porritt, F.R.C.S., at 10, Upper Wimpole Street, W.1 (*not* 3, Regent's Court, N.W.1, as previously announced); Mr. T. Henry Wilson, F.R.C.S., at "Tavistock," 6, Carlisle Road, Eastbourne.

NOTICE—Applications for vacancies advertised should, except where otherwise specified, state name, address, age, nationality, qualifications, and be accompanied by copies of 3 recent testimonials★ with short statement of experience and appointments held. Unless closing date is stated applications should be sent at once.

. ★ *SERVICE MEMBERS may have difficulty in supplying recent testimonials, but this should not deter them from applying.*

R—Male, W—Woman practitioners, liable to military service under the National Service Acts.

B1—Whole-time appointments, usually resident within the senior establishments—e.g., Registrar, R.S.O., etc.

A—Whole-time resident house appointments open to practitioners without previous experience.

B2—Whole-time house appointments not within the senior establishment, usually resident, and usually held by practitioners with six months' experience.

APPOINTMENTS

GOVERNMENT OF BAHRAIN.—The Government of Bahrain, an Arab State in the Persian Gulf, is prepared to receive applications for the post of LADY MEDICAL OFFICER to be in charge of the Women's Hospital and public health work among women. The lady medical officer will be under the State Medical Officer (British), but will be in complete charge of her own department. Previous experience in the East would be an advantage. The work is mainly among subjects of H.H. the Shaikh of Bahrain, but private practice is allowed among the Europeans living in the islands. Only candidates with the right sympathies and interest should apply. The appointment would be for a period of three or four years, commencing March, 1946. Salary £700 to £850 according to age and experience. Practitioners serving in H.M. Forces are invited to apply.* Copies of testimonials and particulars should be forwarded not later than March 23, 1946, to Box 4476, B.M.J.

INDIAN MEDICAL SERVICE. Recruitment of WOMEN MEDICAL OFFICERS.—The Government of India are prepared to recruit a limited number of woman medical officers for service with the Indian Medical Service for so long as their services may be required. Applicants must be British subjects, of not more than 45 years of age, and those selected will be appointed in the rank of Lieutenants. Antedate of seniority may be granted up to a minimum period of 6½ years in respect of resident hospital appointments, higher qualifications, and/or professional experience. The antedate will count for pay and promotion, but, in the case of candidates recruited in this country, higher rank will not be assumed until the date of disembarkation in India. On termination of service, a minimum gratuity is guaranteed to those officers who complete one year of service, viz., Rs. 2,000 to officers whose registrable medical qualification is dated before January 1, 1940, and Rs. 1,000 to those who qualified after that date, plus one month's pay for each further completed year of Army Service. Further particulars regarding rates of pay, etc., may be obtained from the Medical Adviser, India Office, London, S.W.1, or from the Secretary, Military Department, India Office, to whom all inquiries should be addressed.

MINISTRY OF HEALTH REGIONAL BLOOD TRANSFUSION SERVICE. MEDICAL OFFICER. —Applications are invited from registered practitioners of either sex for the post of Medical Officer in the Regional Transfusion Service. The duties include work in the Regional Laboratories situated at Manchester Royal Infirmary, and other centres in the North-Western Region with the Mobile Unit. The salary will be £250 to £350 per annum plus £100 allowance in lieu of board and lodging. Application should be made immediately to Dr. J. F. Wilkinson, Regional Transfusion Officer, Research Department, Manchester Royal Infirmary.

MEDICAL OFFICER OF HEALTH, etc. (Combined Appointment).—Applications are invited from duly qualified medical practitioners possessing a Diploma in Public Health or similar qualification, including those now serving in H.M. Forces, for the following offices to be held as a whole-time joint appointment :—

1. MEDICAL OFFICER OF HEALTH for the Rural Districts of Taunton and Wellington and the Urban District of Wellington. (Population 31,536. Area 110,772 acres).
2. MEDICAL SUPERINTENDENT of Taunton Joint Isolation Hospital (63 beds, including a unit of 3 beds for puerperal fever) and Tuberculosis Sanatorium (20 beds).
3. MEDICAL OFFICER for attendance at the V.D. Clinic of the Somerset County Council, in Taunton.

The total salary for the combined appointments will be £900 per annum, rising by annual increments of £50 to £1,000, plus cost-of-living bonus at present £59 16s. 0d. and a travelling allowance of £130 per annum. Office accommodation, telephone facilities and necessary clerical assistance will be provided at the offices of the Taunton Rural District Council. Further particulars as to the duties and conditions of appointment may be obtained on application to the undersigned. Applications must be sent to the undersigned not later than March 24, 1946. The consent of the Minister of Health has been obtained to the making of this appointment, but his decision is that the appointment must be temporary.—P. O. Cowlishaw, Acting Clerk for Constituent Authorities, Mary Street House, Taunton.

NERVOUS DISEASES HOSPITAL, Belfast.—Applications are invited for the post of HONORARY* PSYCHIATRIST for the above hospital, including practitioners serving in H.M. Forces. Applications with testimonials should be sent to the Secretary, The Nervous Diseases Hospital, Claremont Street, Belfast, not later than March 23, 1946.

BOROUGH OF SCARBOROUGH. MEDICAL OFFICER OF HEALTH AND SCHOOL MEDICAL OFFICER.—Applications are invited from qualified medical practitioners (including serving members of H.M. Forces so qualified) for the above appointment. The person appointed will be required to: (1) perform all the duties imposed on the medical officer of health and school medical officer under relevant Acts, Orders and Regulations; (2) act as medical superintendent of the maternity and child welfare services, and of the Council's isolation hospital; (3) undertake the medical examination of entrants into the Council's Superannuation Scheme; (4) carry out such other duties as may from time to time be prescribed by the Council, and (5) devote his whole time to the duties of the office; not engage in private practice and reside within a radius of three miles from the Town Hall, Scarborough. The appointment is subject to the provisions of Section 110 of the Local Government Act, 1933, and the Sanitary Officers (Outside London) Regulations, 1935. The post is also subject to the provisions of the Local Government Superannuation Act, 1937, and the successful candidate will be required to pass a medical examination. The salary will be at the rate of £900 per annum, rising by annual increments of £50 to a maximum salary at the rate of £1,100 per annum, plus war bonus, which is at present £59 16s. per annum, and a car allowance. In order to allow time for candidates now abroad or in H.M. Forces to apply, the last date for receipt of applications has been fixed at April 1, 1946. Applications should be accompanied by testimonials or the names of three referees and endorsed Medical Officer of Health and School Medical Officer. The consent of the Minister of Health has been obtained to the making of this appointment. Canvassing, either directly or indirectly, will be disqualification.—E. L. Horsfall Turner, Town Clerk, Town Hall, Scarborough.

COUNTY BOROUGH OF SOUTHEND-ON-SEA. Southend Municipal Hospital, Rochford.—Applications are invited from women practitioners for the post of ASSISTANT RESIDENT OBSTETRIC OFFICER (B1) at the Council's Municipal Hospital, Rochford (four miles from Southend-on-Sea). Salary scale £400 by £25 to £500, together with full residential emoluments and war bonus amounting to £24 1s. per annum. Candidates should have had postgraduate experience in midwifery, and preference will be given to those possessing a senior qualification. In fixing the commencing salary, regard will be had to previous experience and qualifications. The Local Government Superannuation Act, 1937, will apply. Application forms obtainable from the Medical Superintendent, Southend Municipal Hospital, Rochford, Essex.—Archibald Glen, Town Clerk, Town Clerk's Office, Southend-on-Sea.

COUNTY BOROUGH OF MIDDLESBROUGH. Hemlington Emergency Hospital.—Applications are invited from registered medical practitioners for the appointment of ASSISTANT RESIDENT MEDICAL OFFICER (B2), at the above hospital (480 beds). Good experience is afforded in both medical and surgical work. The salary is at the rate of £200 per annum, together with full residential emoluments. The successful candidate will be required to pass satisfactorily a medical examination. R and W practitioners who now hold A posts may apply. In the case of R practitioners the appointment will be limited to six months; otherwise twelve months. Applications should be sent to the Medical Officer of Health, Health Department, Municipal Buildings, Middlesbrough, immediately.—Preston Kitchen, Town Clerk, Municipal Buildings, Middlesbrough.

COUNTY BOROUGH OF HASTINGS. Hastings Municipal Hospital.—Applications are invited from registered medical practitioners for the post of ASSISTANT MEDICAL OFFICER (B2) (female). The hospital contains 350 beds, including a Children's Block and a Maternity Unit of 28 beds and is a group A1 Hospital under the Government's Emergency Hospital Service. Candidates must be fully qualified registered medical practitioners and should have held a previous resident hospital appointment. The number of confinements at the hospital during the last year was 450, and the candidate will have every opportunity of gaining experience in maternity work, normal and abnormal, also ante-natal and post-natal clinics. Preference will be given to candidates with practical experience of general medicine and anaesthetics. The person appointed will give her whole time to the service of the Council in accordance with the terms of her appointment. Salary £325 per annum, with apartments, board, and laundry. W practitioners holding A posts may apply. The appointment is for one year and is determinable by one month's notice on either side. Applications, on forms to be obtained from me, should be returned as soon as possible.—D. W. Jackson, Town Clerk and Director of Social Welfare, Town Hall, Hastings.

COUNTY BOROUGH OF BIRKENHEAD. Department of the Medical Officer of Health, Birkenhead Municipal Hospital. RESIDENT SURGICAL OFFICER (B1) (male or female).—Applications are invited from registered medical practitioners for the appointment of Resident Surgical Officer at the Birkenhead Municipal Hospital, which will shortly become vacant. The appointment is tenable for a period not exceeding twelve months. The duties of a Resident Surgical Officer are mainly surgical and obstetrical, and preference will be given to candidates who have had surgical and obstetrical experience in a municipal or voluntary hospital. Suitably qualified R and W practitioners now holding B2 appointments may apply. Applications from R practitioners now holding B1 appointments cannot be considered unless they have been rejected by the R.A.M.C., or for other reasons are not eligible for military service. Alien practitioners will be eligible for appointment. The salary attached to the appointment will be at the rate of £300 per annum plus war bonus, and the appointment will be subject to the regulations of the Council regarding holidays, sick pay, etc. Forms of application and further particulars relating to the appointment may be obtained from the Medical Officer of Health, Dr. D. Morley Mathieson, 9, Hamilton Square, Birkenhead, to whom they should be returned as soon as possible, endorsed "Resident Surgical Officer."—E. W. Tame, Town Clerk.

COUNTY BOROUGH OF MIDDLESBROUGH. TEMPORARY ASSISTANT MEDICAL OFFICER OF HEALTH AND RESIDENT MEDICAL OFFICER.—Applications are invited from registered medical practitioners not already in whole-time Public Health employment for the appointment of Temporary Assistant Medical Officer of Health and Resident Medical Officer at the Municipal Maternity Hospital. The consent of the Ministry of Health has been obtained to the filling of the temporary appointment. The successful candidate will be required to reside at the Municipal Maternity Hospital (50 beds), and the duties will also include attendance at the Ante-natal, Post-natal and Infant Welfare Clinics, together with other general duties in the Maternity and Child Welfare Department. Applicants should have had previous experience in Midwifery and Diseases of Children, and will be required to work under the direction of the Medical Officer of Health. The commencing salary will be at the rate of £550 per annum, with residence, board and laundry valued at £150 per annum, making £700 in all, and rising, subject to satisfactory service, by annual increments of £50 to a maximum of £850. The appointment is subject to the provisions of the Local Government Act, 1937, and is terminable by three months' notice on either side. Applications to be sent to the Medical Officer of Health, Municipal Buildings, Middlesbrough, not later than Tuesday, December 4, 1945.—Preston Kitchen, Town Clerk, Municipal Buildings, Middlesbrough.

COUNTY BOROUGH OF BIRKENHEAD. Department of the Medical Officer of Health. Birkenhead Municipal Hospital (560 beds). RESIDENT MEDICAL OFFICER (A), male or female.—Applications are invited from registered medical practitioners, male or female, for the above appointment, which will be vacant shortly, including practitioners within three months of qualification who are liable for service under the National Service Acts. If held by a practitioner who is liable under these Acts, the appointment will be for a period of six months, otherwise it will be for one year. Applications from alien practitioners will be considered. Salary at the rate of £200 per annum, plus bonus and full residential emoluments. Application forms to be obtained from Dr. D. Morley Mathieson, the Medical Officer of Health, 9, Hamilton Square, Birkenhead, to whom they should be returned as soon as possible after completion.—E. W. Tame, Town Clerk, Town Hall, Birkenhead.

COUNTY BOROUGH OF SOUTHEND-ON-SEA —Applications are invited from registered medical practitioners, male and female, including R and W practitioners who now hold A posts, for the appointment of RESIDENT ASSISTANT MEDICAL OFFICER, Grade II (B2), at the Southend Municipal Hospital, Rochford, Essex. Previous experience in the administration of anaesthetics is desirable. The salary is at the rate of £325 per annum with full residential emoluments, plus war bonus. The person appointed will be liable to pay superannuation contributions if the provisions of the Local Government Officers' Superannuation Acts are applicable. To R practitioners the appointment will be limited to six months; otherwise for a period of one year and subject to one month's notice on either side. The appointment becomes vacant January 1, 1946. Application forms obtainable from the Medical Superintendent, Southend Municipal Hospital, Rochford, Essex, should be returned as soon as possible.—Archibald Glen, Town Clerk, Town Clerk's Office, Southend-on-Sea.

IMPORTANT—All applicants should read the notice at the top of page 9 about qualifications required.

CITY AND COUNTY OF NEWCASTLE-UPON-TYNE. Newcastle General Hospital (900 beds). HOUSE SURGEON (B2) to the Neurosurgical Department.—Applications are invited from registered medical practitioners, male and female, for the above post, now vacant, including R and W practitioners who now hold A posts. The appointment is tenable for six months and the salary is at the rate of £250 per annum, plus cost-of-living bonus and full residential emoluments.

Applications are also invited from registered medical practitioners, male and female, for the appointments of TWO HOUSE PHYSICIANS (A) and FOUR HOUSE SURGEONS (A), to become vacant between January 16 and 31, 1946. The appointments will be for a period of six months. Salary at the rate of £150 per annum, with full residential emoluments and cost-of-living bonus. Practitioners within three months of qualification and liable under the National Service Acts may apply.

Applications are also invited from registered medical practitioners, male and female, for the appointment of HOUSE PHYSICIAN (A) to the Children's Department, to become vacant on February 1, 1946. The department is actively associated with, and shares staff with, the Department of Child Health of Durham University, and the post offers exceptional opportunities for gaining experience in many aspects of paediatrics. The appointment is tenable for a period of six months and the salary is at the rate of £150 per annum, plus cost-of-living bonus and full residential emoluments. Practitioners within three months of qualification and liable under the National Service Acts may apply.

Applications for each appointment should be forwarded to the Medical Officer of Health, Town Hall, Newcastle-upon-Tyne.

CITY AND COUNTY OF BRISTOL. Department of Public Health. ASSISTANT RESIDENT MEDICAL OFFICER.—Applications are invited from registered medical practitioners, male or female, for the immediate appointment of Assistant Resident Medical Officer (B2) at Ham Green Infectious Disease Hospital and Sanatorium (500 beds), including R and W practitioners who now hold A posts. If held by an R practitioner the appointment will be limited to six months. Otherwise it will be held for a period of one year. Salary £200 per annum, plus full residential emoluments. Application forms may be obtained from the undersigned, to whom they must be returned, accompanied by copies of not more than three recent testimonials, forthwith.—R. H. Parry, Medical Officer of Health, Kenwith Lodge, Westbury Park, Bristol, 6.

CITY OF STOKE-ON-TRENT. City General Hospital. ASSISTANT RESIDENT MEDICAL OFFICERS.—Applications are invited from registered medical practitioners (single—male or female), including R and W practitioners who now hold A posts, for two appointments of Assistant Resident Medical Officer (B2), at the City General Hospital, Stoke-on-Trent. If offered to R practitioners, the appointment will be limited to a period of six months, otherwise they will be for a period of one year. The salary is at the rate of £250 per annum, plus bonus, with full residential emoluments. The hospital, which is an emergency hospital, has approximately 1,200 beds, and there is excellent scope for medical, surgical and obstetrical work. Applications, endorsed "Medical Officer—City General Hospital," should be sent to the undersigned immediately.—Harry Taylor, Town Clerk.

CITY OF LEEDS. POLICE SURGEON.—The Watch Committee invite applications from qualified and registered medical practitioners (including those now serving in H.M. Forces) for the post of Police Surgeon. The salary for the post is £1.200 per annum rising by annual increments of £50 to £1,400 per annum, with motor car allowance. Particulars as to the duties of the appointment may be obtained from the Town Clerk, Civic Hall, Leeds, 1. The person appointed will be required to devote his whole time to the duties of the office and to pay into the General Rate Fund all fees, emoluments or other payments whatsoever which may be received in connexion with the appointment. The appointment will be subject to the provisions of the Local Government Superannuation Act, 1937, and to the passing of a medical examination. Applications, endorsed "Police Surgeon" must be delivered at my office, Room 57, Civic Hall, Leeds, 1, not later than 12 noon on March 30, 1946 Canvassing in any form either directly or indirectly will be a disqualification.—O. A. Radley, Town Clerk.

CITY OF ABERDEEN. REGIONAL TUBERCULOSIS MEDICAL OFFICER.—Applications (including those from Medical Practitioners serving in H.M. Forces) are invited for the post of Regional Tuberculosis Medical Officer for the City of Aberdeen and for the Counties of Aberdeen and Kincardine. The salary payable shall be not less than £1,000 per annum. In addition a war bonus amounting at present to £60 per annum is payable. The selected candidate will be required to pass a medical examination for superannuation purposes before appointment. A memorandum setting forth the duties, conditions of appointment etc., and the official form of application may be obtained from the undersigned, with whom the said form, duly completed, with copies of testimonials, should be lodged on or before March 30, 1946.—D. B. Gunn, Town Clerk, Town House, Aberdeen.

CITY OF PORTSMOUTH, St. James Hospital for Mental and Nervous Disease. SENIOR ASSISTANT MEDICAL OFFICER (B1) (male or female).—Applications are invited from suitably qualified practitioners holding B2 appointments or those holding B1 appointments who have been rejected by the R.A.M.C. for the post of Senior Assistant Medical Officer. The commencing salary for this post is £500 per annum plus full residential emoluments valued at £150 per annum with wartime bonus of £24 14s. per annum and an extra £50 per annum for holders of the D.P.M., rising by £50 per annum to £700.

This appointment is at present on a temporary basis, but when re-advertised on a permament basis the successful applicant will be eligible to apply. There is a comprehensive Mental Health Service. for the City of Portsmouth based on the hospital. The post involves work in all branches of psychiatry, including out-patient clinics, psychoses, psychoneuroses, delinquency and child guidance.

SECOND ASSISTANT MEDICAL OFFICER (B1) (male or female).—Applications are invited from suitably qualified practitioners holding B2 appointments or those holding B1 appointments who have been rejected by the R.A.M.C. for the post of Second Assistant Medical Officer. The commencing salary for this post is £400 per annum plus full residential emoluments valued at £150 per annum with wartime bonus of £24 14s. per annum and an extra £50 per annum for the holders of the D.P.M., rising by £50 per annum to £600

This appointment is at present on a temporary basis, but when re-advertised on a permanent basis the successful applicant will be eligible to apply. There is a comprehensive Mental Health Service for the City of Portsmouth based on the hospital. The post involves work in all branches of psychiatry, including out-patient clinics, psychoses, psychoneuroses, delinquency and child guidance.

Applications for each post should be addressed to Dr. Thomas Beaton, O.B.E., Medical Superintendent, St. James Hospital, Milton, Portsmouth.—Frederick Sparks, Town Clerk and Clerk to St. James Hospital Visiting Committee, Municipal Offices, Royal Beach Hotel, Southsea.

CITY OF LIVERPOOL. PART-TIME VISITING RADIOLOGIST.—Applications are invited from registered medical practitioners for the permanent appointment of a part-time visiting Radiologist to Alder Hey Children's Hospital and Belmont Road Hospital. Applications from Service candidates are invited. The salary is at the rate of £500 per annum and all fees received in connexion with the appointment are to be handed over to the City Council. The successful candidate will be required to attend for six sessions per week to be arranged between the two hospitals. Applicants must possess the Diploma in Medical Radiology and Electrology, and have had considerable experience in radiological duties. The appointment will be made in accordance with the Standing Orders of the City Council and will be determinable by three calendar months' notice on either side. Canvassing members of the City Council, either directly or indirectly, will be regarded as a disqualification. Applications should be endorsed "Visiting Radiologist" and sent to the undersigned so as to be received not later than March 30, 1946. The consent of the Minister of Health has been obtained to the making of this appointment.—W. H. Baines, Town Clerk, Municipal Buildings, Dale Street, Liverpool, 2.

CITY OF LIVERPOOL. Belmont Road Hospital, Belmont Road, Liverpool, 6 (1,930 beds). RESIDENT ASSISTANT MEDICAL OFFICER (B2).—Applications are invited from registered medical practitioners, male and female, for the above appointment, including R and W practitioners who now hold A posts. If held by an R practitioner, the appointment will be limited to six months, otherwise it will be for a period of twelve months. The hospital is mainly for the treatment of chronic sick and infirm. There is also a large department for the treatment of skin diseases. The salary is at the rate of £350 per annum with full residential emoluments and cost of living bonus. All fees received in connexion with the appointment to be handed over to the City Council. The appointment will be made in accordance with the Standing Orders of the City Council and will be determinable by one month's notice on either side. Applications should be endorsed "Resident Medical Officer" and sent to the undersigned forthwith.—W. H. Baines, Town Clerk, Municipal Buildings, Dale Street, Liverpool, 2.

CITY OF LEEDS. Public Health Department. St. James's Hospital. ORTHOPAEDIC HOUSE SURGEON (B2) (male).—Applications are invited from registered medical practitioners for the post of Orthopaedic House Surgeon (B2) for the above Municipal Hospital. Candidates must have had previous orthopaedic experience. R practitioners who now hold A posts may apply, when the appointment will be limited to six months; otherwise it will be for a period of twelve months. The salary is at the rate of £200 per annum, plus cost-of-living bonus, together with full residential emoluments. Applications endorsed Orthopaedic House Surgeon to be forwarded to the undersigned.—J. Johnstone Jervis, Medical Officer of Health, Public Health Department (Hospitals Administration Section), 12, Market Buildings, Vicar Lane, Leeds, 1.

CITY OF BIRMINGHAM. TEMPORARY ASSISTANT MEDICAL OFFICER OF HEALTH. Maternity and Child Welfare.—Applications are invited from qualified medical women to act as Temporary Assistant Medical Officer for the Maternity and Child Welfare Department. The medical officer appointed will attend ante-natal and children's clinics and will undertake duties at one of the city maternity homes. This will involve relieving the senior medical officer on alternate nights and week-ends. She should have had previous obstetric experience. The post is non-resident and the salary scale will be £575 by £25 to £775, plus cost-of-living bonus. The commencing salary within the scale will be according to experience. The consent of the Ministry of Health has been given to this appointment, but persons already in whole-time public health employment by local authorities will not be eligible to make application. The successful applicant will be required to undergo a medical examination and to join the City of Birmingham Superannuation Scheme. Applications to be made on a form obtainable from the Medical Officer of Health, Council House, Birmingham, 3, and returnable to him on or before December 12, 1945.

CITY OF BRADFORD.—Applications are invited for the permanent position of MEDICAL OFFICER OF HEALTH of the City at a salary of £1,750 a year, rising by annual increments of £50 to £2,000. The person appointed must devote his whole time to the service of the Council, and a copy of the duties required to be performed may be obtained on application to the undersigned. The appointment is subject to the Local Government Superannuation Act, 1937, and the successful candidate will be required to undergo a medical examination. Applications should reach me not later than February 28, 1946. Candidates serving overseas may furnish the names of three referees in lieu of forwarding copies of testimonials, and should indicate where a telegram, or cable, will reach them if selected for interview. The consent of the Minister of Health has been obtained to the making of this appointment. Canvassing will be a disqualification.—N. L. Fleming, Town Clerk, Town Hall, Bradford.

CITY OF CARLISLE. City General and Fusehill Emergency Hospitals, Carlisle (100 civilian beds and 180 E.M.S.).—Applications are invited for the following appointment: JUNIOR RESIDENT MEDICAL OFFICER (A) to assist in care of civilian beds and for orthopaedic and general surgical duties in the adjacent E.M.S. Fracture A Hospital. Practitioners within three months of qualification who are liable for service under National Service Acts may apply. Appointment will be for a period of six months from December 1, 1945. Salary £200 per annum, with full residential emoluments. Applications should be sent to the Acting Medical Officer of Health, 22, Fisher Street, Carlisle, as early as possible.

CITY OF NORWICH. Woodlands Hospital (311 beds). ASSISTANT RESIDENT MEDICAL OFFICER (B2).—Applications are invited from registered medical practitioners for the appointment of Assistant Resident Medical Officer (B2), including R and W practitioners who now hold A posts. If held by an R practitioner, the appointment will be limited to six months, otherwise it will be for a period of one year. The salary is at the rate of £250 per annum, with full residential emoluments. Further particulars of appointment to be obtained from the Senior Medical Officer, Woodlands Hospital, Bowthorpe Road, Norwich, and to whom applications should be sent.—Bernard D. Storey, Town Clerk, City Hall, Norwich.

COUNTY BOROUGH OF PRESTON. MEDICAL OFFICER OF HEALTH.—The Council invite applications for the appointment of Medical Officer of Health, Medical Officer to the Port Health Authority, and Superintendent Schools Medical Officer. Salary £1,200 per annum, rising by annual increments of £50 to £1 350 per annum, plus bonus. The consent of the Minister of Health has been obtained to the making of the appointment, which is subject to the provisions of Section 110 of the Local Government Act, 1933, and of the Sanitary Officers (Outside London) Regulations, 1935. Candidates must be registered medical practitioners, have practical experience of the duties of the office and possess the qualifications required by statute and the regulations of the Minister of Health. Applications to be delivered to me not later than March 31, 1946. Applications from persons at present serving in H.M. Forces will be considered. Canvassing will disqualify.—Herbert E. Nutter, Town Clerk.

COUNTY BOROUGH OF BRIGHTON.—A vacancy occurs with the Brighton Municipal Hospital Services for a B2 post as RESIDENT JUNIOR MEDICAL OFFICER, and applications are invited from registered medical practitioners of either sex, including R and W practitioners who now hold A posts. If held by an R or W practitioner, the appointment will be limited to six months, otherwise it will be for a period not exceeding one year. The person appointed will be resident at the Borough Sanatorium and duties will include work on the infectious disease wards and certain anaesthetic duties at the Municipal Hospital. Salary £300 per annum, together with residential allowances valued, for the purposes of superannuation, at £150 per annum plus cost-of-living bonus. Further details and forms of application may be obtained from the undersigned.—Stanley J. Firth, Medical Director, Municipal Hospital, Elm Grove, Brighton, 7.

IMPORTANT—All applicants should read the notice at the top of page 9 about qualifications required.

Applications should be sent to the undersigned as soon as possible.—A. Stanley Brunt, General Supt and Secretary.

ROYAL HALIFAX INFIRMARY.—Wanted, THIRD HOUSE SURGEON (A) (male, unmarried). Practitioners within three months of qualification who are liable for service under the National Service Acts may apply. The appointment is for six months, at a salary of £175 per annum. Applications should be sent to the undersigned.—A Midgley, Secretary

IMPORTANT—All applicants should read the notice at the top of page 9 about qualifications required.

ROYAL VICTORIA INFIRMARY, Newcastle-upon-Tyne. APPOINTMENT OF MATRON.—The House Committe of the Royal Victoria Infirmary wish to proceed with the appointment of a Matron to succeed Miss Charteris, who is retiring at an early date. The infirmary is a general hospital with special departments and a recognized training school for nurses. It is the teaching hospital for the University of Durham. The infirmary has a present total of 810 beds. The House Committee desire that this appointment should offer new opportunities to someone who is anxious to advance nursing practice and nursing education, and for these purposes have arranged to relieve the Matron of all duties within the hospital other than those directly related to nursing. She will be provided with adequate technical, educational and secretarial staff. She will be encouraged to study in practice and by inquiry the nursing needs of the patient on the one hand and the needs of the nurses on the other, so that new methods and standards of nursing may be kept constantly in mind throughout the hospital. She will be given the opportunity of travel and of using all other means of keeping abreast of modern advances in nursing and of educational methods in other fields. The House Committee will welcome applications for this appointment from as wide a field as possible, including those who have not had recent nursing experience and from those with medical and other academic qualifications, and every opportunity will be given for applications from those who are at present in H.M. Forces. The salary will be within the Rushcliffe scale, subject to modification for special qualification or experience. Terms and conditions of the appointment will be discussed at interview. Form of application, together with more detailed particulars of terms and conditions of appointment, may be had on application to the undersigned.—A. W. Sanderson, House Governor.

ROYAL HOSPITAL, Wolverhampton. (Incorporated under Royal Charter). (500 beds). ASSISTANT RADIOLOGIST (DIAGNOSTIC).—Notice is hereby given that the Board of Management of, the Royal Hospital, Wolverhampton, wish to let it be known that a vacancy will shortly occur on the Honorary Staff of the Royal Hospital, for an Assistant Radiologist (Diagnostic). The Royal Hospital, Wolverhampton, is an associated hospital of the University of Birmingham Medical Faculty for Clinical Teaching. Inquiries will be welcomed from prospective candidates, including practitioners serving in H.M. Forces, who must hold a Diploma in Radiology. The vacancy will be advertised early in the new year, and the appointment probably made some time after April 1, 1946.—W. Cockburn, House Governor.

ROYAL SHEFFIELD INFIRMARY AND HOSPITAL.—Applications are invited from registered medical practitioners, male and female, including Medical Officers recently demobilized from H.M. Forces, for the post of CASUALTY OFFICER (B1) with salary at the rate of £150 per annum resident. Applicants should have held house appointments and had experience. Suitably qualified R and W practitioners holding B2 appointments and also R practitioners holding B1 appointments who have been rejected by the R.A.M.C. are invited to apply. Applications to be forwarded immediately to the undersigned.—Percy N. Glass, General Superintendent, Royal Infirmary, Sheffield, 6.

ROYAL SOUTH HANTS AND SOUTHAMPTON HOSPITAL, Southampton (255 beds).—Applications are invited from registered medical practitioners for the appointment of RESIDENT MEDICAL AND SURGICAL OFFICER (B1), vacant forthwith, at the Hospital's Annexe at Romsey (75 beds). The appointment will be for a period of six months in the first instance. Salary is at the rate of £350 per annum, with full residential emoluments. Certain facilities are available to married applicants. Suitably qualified R practitioners holding B2 appointments, also those B1 and rejected by the R.A.M.C. may apply. Applications should be forwarded as soon as possible to Frank Jennings, House Governor and Secretary.

ROYAL WATERLOO HOSPITAL, Waterloo Road, London, S.E.1. HONORARY ASSISTANT SURGEON.—Applications, including those from practitioners serving in His Majesty's Forces, are invited for the post of Honorary Assistant Surgeon. Candidates must be Fellows of the Royal College of Surgeons, England. Applications should be sent to the undersigned on or before April 1, 1946.—J. H. Teasdale, Secretary.

ROYAL FREE HOSPITAL, Gray's Inn Road, W.C.1.—Applications are invited from registered medical practitioners, male and female, for the appointment of HOUSE SURGEON (B2), for a period of six months, to become vacant January 1, 1946, including R practitioners who now hold A posts. Salary £200 per annum. Applications should be sent to the undersigned on or before December 7, 1945.—Richard T. Bartley.

ROYAL UNITED HOSPITAL, Bath, HOUSE PHYSICIAN (A).—Applications are invited for the above appointment. Salary at the rate of £150 per annum, with board, residence, etc. Practitioners within three months of qualification and liable under the National Service Acts may apply, when appointment will be for a period of six months. Applications to the undersigned.—J. Lawrence Mears, Secretary-Superintendent.

ROYAL CRIPPLES HOSPITAL, Birmingham. One of the largest Orthopaedic Hospitals in the country, with 338 beds for acute patients and large Out-patient Department in Birmingham where 126,153 attendances were made in 1944: The Hospital is also responsible for staffing Out-patient Clinics in a number of adjoining towns.—Applications are invited from registered medical practitioners, including R and W practitioners who now hold A posts, for the appointment of a RESIDENT HOUSE SURGEON (B2), vacant January next. Appointment will be for six months. Commencing salary not less than £200 per annum, with full residential emoluments. Applications to the Secretary, 80, Broad Street, Birmingham, 15.

ROYAL SEA-BATHING HOSPITAL, Margate (for Surgical Tuberculosis).—Applications are invited from legally qualified and registered candidates for the post of ASSISTANT MEDICAL SUPERINTENDENT (male) at the above hospital, at a salary of £500 per annum, with full board and laundry. The appointment will be tenable for two years. Candidates, who must be single, should have held a resident surgical appointment in a general hospital and have had some experience of pathology and orthopaedic surgery. Officers demobilized from H.M. Forces, or about to be demobilized in the near future, are invited to apply. Applications should be sent to the Secretary, R.S.B.H. Offices, 2, High Street, Bracknell, Berkshire, as soon as possible.

ROYAL SUSSEX COUNTY HOSPITAL, Brighton.—Applications are invited from registered medical practitioners for the appointment of SENIOR RESIDENT MEDICAL OFFICER AND RESIDENT SURGICAL OFFICER (B1), to become vacant on February 1, 1946. Applicants should have held house appointments and had surgical experience. Suitably qualified R practitioners holding B2 appointments are invited to apply. Applications from R practitioners now holding B1 appointments cannot be considered unless they have been rejected by the R.A.M.C. Salary is at the rate of £300 per annum with full residential emoluments. Applications should be forwarded to the undersigned by December 16 next.—L. L. W. Lancaster-Gaye, Secretary-Superintendent.

ROYAL SOUTH HANTS AND SOUTHAMPTON HOSPITAL, Southampton (255 beds).—Applications are invited from registered medical practitioners, male, including R practitioners who now hold A posts, for the appointment of CASUALTY OFFICER AND HOUSE SURGEON (B2) to the E.N.T. Department. The appointment will be for a period of six months. Salary is at the rate of £200 per annum, with full residential emoluments. Applications should be forwarded immediately to Frank Jennings, House Governor and Secretary.

ROYAL HAMPSHIRE COUNTY HOSPITAL, Winchester (432 beds).—Applications are invited from registered medical practitioners, men and women, for the appointment of HOUSE SURGEON (A), vacant immediately. Salary is at the rate of £175 per annum, with full residential emoluments. Practitioners within three months of qualification and liable under the National Service Acts may also apply, when appointment will be for a period of six months. Applications should be sent to D. M. Stanbury, Acting Superintendent and Secretary.

SOUTHEND-ON-SEA GENERAL HOSPITAL.—Applications are invited from registered medical practitioners, including registered practitioners who now hold A posts, for the appointment of HOUSE PHYSICIAN (B2), vacant immediately. The appointment will be for six months. Salary at the rate of £150 per annum, with full residential emoluments. Applications to be sent immediately to the undersigned.—John Williams, House Governor and Secretary.

SOUTH LONDON HOSPITAL FOR WOMEN, Clapham Common, S.W.4. HOUSE SURGEON (A).—Applications are invited from registered medical women practitioners for the above appointment to become vacant on January 1, 1946. The appointment will be for a period of six months. Salary is at the rate of £100 per annum, with full residential emoluments. Applications should be sent to the Secretary at the hospital as soon as possible.

STOCKPORT INFIRMARY (167 beds).—Applications are invited from registered medical practitioners for the post of ASSISTANT RESIDENT SURGICAL OFFICER AND CASUALTY OFFICER (B2), now vacant, including R practitioners who now hold A posts. Salary is at the rate of £200 per annum, with full residential emoluments, and the appointment is for six months. Applications to be sent to the undersigned immediately.—H. G. Price, Secretary-Superintendent.

SALFORD ROYAL HOSPITAL.—Applications are invited for the post of RESIDENT SURGICAL OFFICER (B1). Salary £250 plus the usual residential emoluments. Appointment for one year. R practitioners holding B2 posts, also those holding B1 and rejected by the R.A.M.C. may apply. Applications to be made on the prescribed form obtainable from the General Superintendent at the hospital.

ST. PETER'S HOSPITAL FOR STONE, ETC., Henrietta Street, Covent Garden, W.C.2.—The appointment of CLINICAL ASSISTANTS to the undermentioned members of the honorary staff, who attend the out-patient department at the times indicated, will be considered at an early date for the six months commencing January 1, 1946. YOUNG LADY, 6 years' experience hospital (out-patients) and welfare work, excellent testimonials, requires similar DAY WORK or with private doctor, London.—Box 4766, B.M.J.

MISCELLANEOUS

EXCELLENT SET PATHOLOGY SLIDES, (110), various systems, good for study, seen London or sent approval, price £10.—Box 4756, B.M.J.

FOR SALE, Hanovia Centrosol U.V. LAMP. Ionisation outfit (A and H.). Gas and air anaesthetic apparatus (B.O.Co.). Almost unused. Pre-war.—Box 4716, B.M.J.

FOR SALE, APPARATUS. High Frequency, Violet and Healer Rays. To be sold privately.—Major T. Storey, Warner Lodge, Bush Hill, London, N 21. Tel. Laburnum 3857.

FOR SALE, dual purpose MERCURY VAPOUR LAMP, excellent condition. 220 volts d.c. £20 or near offer. Also unused axis traction forceps.—MAIda Vale 5124.

FOR SALE, infra red ray LAMP, complete full length stand, two elements, as new, London district, £10 10s.—Box 4758, B.M.J.

FOR SALE. CYSTOSCOPE. Ringleb pattern for examination, with battery. New, £10. Many other instruments.—Stiell, 10, Lucy Tower Street, Lincoln.

HISTOLOGY CASE, 150 slides, normal tissues, beautiful specimens, £10 10s. Also 50 slides pathology, mahogany case, £5 5s.—Box 4755, B.M.J.

LATEST ZEISS BINOCULAR MICROSCOPE with numerous accessories, including Epilight attachment. Seen Harley Street. £300.—Box 4751, B.M.J.

MICROSCOPE (BAKER) for sale at Bath, movable stage, centring sub-stage, eyepieces 3 and 5, objectives (Leitz) 3, 6, 1/12, also 1/12 Reichart, and one inch (Baker). Concentric condenser (Leitz) with funnel stop. All in good order. Mahogany case.—Cowan, 44, Combe Park, Bath.

RADIANT HEAT CABINET BATH, approx. 4 ft. by 4 ft., polished mahogany, incorporating 40 separately switched lamps. Apparently never used but name plate removed. Perfect condition. Seen London. First reasonable offer.—Box 4750, B.M.J.

WANTED, SECOND-HAND SURGICAL INSTRUMENTS, furniture for surgery and consulting room, blood pressure apparatus, electric diagnostic sets, ophthalmoscopes, auriscopes, microscopes, etc.—Particulars to A. Fleming & Co. (Succrs.), 51, Mortimer Street, London, W.1. Telephone: Mus 6292).

COMPRI-VENA (1937), Ltd.—The care and after-care of Varicose Veins.—In the treatment of Varicose Veins where leg support is prescribed, Compri-Vena gives meticulous attention to instructions. They will glady supply particulars of Surgical Stockings and the service they provide.—38, South Molton Street, W.1. MAYfair 0732.

DOCTORS' WATCHES.—Franklands can still supply Gold Watches. Write for particulars.—E. J. Frankland & Co., Ltd., Marle House, South Godstone, Surrey; or London Showroom, New Bridge Street House, 30-34, New Bridge Street, Ludgate Circus, E.C.4

"EVERBRITE" RECHARGEABLE TORCH. Recharged at home from your mains. No battery required. Several hours continuous light. Thousands in use. Fully guaranteed. The "King of Pocket Lamps." Direct or from dealers. Send for interest-leaflet K. 150.—Runbaken Electrical Products, Manchester, 1.

MEDICAL PHOTOGRAPHS and drawings for illustration, records, etc.—Write for particulars, Eric O. Sonntag, 159, Bickenhall Mansions, Baker Street, London, W.1. WELbeck 8860.

MICROSCOPES WANTED for important work. Send particulars with price required.—Wallace Heaton, Ltd., 127, New Bond Street, London, W.1.

WIGMORE'S, LTD. 63, Baker St., London, W.1. (Welbeck 5668) DISPENSING OPTICIANS by appointment to Western Ophthalmic Hospital, Marylebone Road, London, N.W.1. Doctors' prescriptions accurately dispensed.

THE IN-VITRO SENSITIVITY OF H. INFLUENZAE TO PENICILLIN

WITH SPECIAL REFERENCE TO MENINGEAL STRAINS OF PITTMAN'S TYPE b

BY

M. GORDON, M.D., M.Sc.

AND

K. ZINNEMANN, M.D.

Lecturer in the Department of Pathology and Bacteriology, School of Medicine, University of Leeds

Since the publication of Fleming's (1929) original paper on the antibacterial action of penicillin it has been generally accepted that *H. influenzae* is an organism on which penicillin has little or no bacteriostatic effect. Though Fleming and Maclean later (1930) observed some inhibitory effect on the growth of *H. influenzae* with higher concentrations of penicillin, this was not stressed, and Fleming (1932, 1937) includes *H. influenzae* in the list of organisms practically insensitive to penicillin. Hobby, Meyer, and Chaffee (1942) also emphasize this insensitivity, and Mortara, Feiner, and Levenkron (1944) obtained growth of *H. influenzae* with concentrations as high as 2 units of penicillin per c.cm. of medium, though apparently they tested only one strain.

We were recently concerned with the isolation of *H. influenzae* from nasopharyngeal swabs, using the techniques described by Fleming (1930), of incorporating penicillin as a selective agent in the medium. During preliminary observations it was found that the growth of some strains of *H. influenzae* were completely inhibited at the higher concentrations used. In view of the possibility of treating meningitis cases due to *H. influenzae* with penicillin, it was decided to investigate more fully the sensitivity to penicillin of the comparatively large number of *H. influenzae* strains in our possession.

Technique

Seven lots of heated blood-agar medium were prepared with oxalated horse blood. Before pouring these on to plates they were cooled to below 50° C. and a solution of calcium or sodium penicillin was incorporated in the media to give concentrations of 0.1, 0.25, 0.5, 1, 2.5, and 5 units of penicillin per c.cm. of medium respectively. No penicillin was added to the seventh lot of heated blood agar, which served as a control.

In all, 61 strains of *H. influenzae* were tested. Fifteen were isolated from nasopharyngeal swabs, 28 were strains isolated from bronchial secretions (Allison, J. Gordon, and Zinnemann, 1943), and 16 were known to have been isolated from the cerebrospinal fluid. Fourteen of these latter strains were of Pittman (1931) Type b, and two, although isolated from cases of meningitis, presented the characteristics of rough strains commonly present in the respiratory tract (Pittman, 1933; Mulder, 1939; J. Gordon, Woodcock, and Zinnemann, 1944). Two *H. influenzae* Type b stock strains kindly sent to us by Miss Pittman and Miss Straker were also included. Four of the Type b strains had undergone dissociation from the smooth to the rough phase during continued subculture over a long period.

Heavy broth suspensions of these organisms of approximately equal opacity were inoculated on to the experimental plates. Suspensions of the Oxford standard staphylococcus and the streptococcus 4241, used as an additional standard in this laboratory, were also inoculated on to each plate to act as controls for the inhibiting action of penicillin. The plates were incubated at 37° C. for 48 hours, and in the case of markedly inhibited growths subcultures were made to heated blood-agar plates to test viability.

Results

Respiratory Strains.—From Table I it is seen that the growths of 31 out of 43 strains were completely inhibited by a concentration of 2.5 units of penicillin per c.cm. of medium, and even in a concentration of only 1 unit per c.cm. the growths of 11 strains were completely and of 18 markedly inhibited. Only 7 strains showed growths with 5 units of penicillin per c.cm. of medium, and these were all markedly inhibited.

* Stock strain.

+++ = Heavy growth. ++ = Moderate growth. + = Markedly inhibited growth. Figures denote numbers of colonies when less than 50. 0 = No growth.

Meningeal Strains.—Table II shows that with 2.5 units of penicillin per c.cm. of medium the growths of 16 out of 18 meningeal strains were completely inhibited and those of the other 2 strains showed marked inhibition. Even with 0.5 unit per c.cm. of medium the growths of 3 strains were completely inhibited and those of 6 markedly so. One of the strains (Morris) varied in its sensitivity to penicillin, as in earlier experiments it showed inhibited growths even up to 5 units of penicillin per c.cm. of medium.

Discussion

These experiments establish the fact that *H. influenzae* strains are not insensitive to penicillin, though the sensitivity is very much lower than that of staphylococcal and streptococcal strains. This finding supports the results obtained by Hobby (1944). She investigated the action of penicillin on a number of Gram-negative organisms previously considered to be insensitive to penicillin. *H. influenzae* was not included in her experiments. She states that "it is apparent that penicillin exerts an antibacterial action against Gram-negative as well as Gram-positive organisms."

The practical application of these observations is restricted to cases of *H. influenzae* meningitis at the present time, since the role of *H. influenzae* as a pathogen in the respiratory tract is still under discussion. The mortality in cases of *H. influenzae* meningitis, treated non-specifically, is about 97% (Lindsay, Rice, and Selinger, 1940). Treatment with sulphonamides appears to have reduced this mortality, and, in combination with specific rabbit antiserum therapy, has lowered it further to 26% of 75 cases quoted (Alexander, 1943). Unfortunately type-specific rabbit antiserum is not available in this country, and penicillin as an additional means of treating *H. influenzae* meningitis appears to be worthy of trial. Penicillin, however, does not seem to penetrate the meninges readily, Fleming (1943) having shown that after intramuscular administration the concentration of penicillin in the cerebrospinal fluid is only one-quarter to one-half of that in the serum. For the most effective treatment of meningitis due to *H. influenzae* it would be necessary, therefore, to administer penicillin intrathecally in addition to the usual intramuscular or intravenous methods. A concentration of at least 2.5 units per c.cm. in the cerebrospinal fluid should be reached at the outset. Later, more exact determination of the penicillin sensitivity of the particular *H. influenzae* strain isolated and assay of the penicillin content of the cerebrospinal fluid should serve as a guide to the further dosage to be given.

Summary

Fifteen *H. influenzae* strains from the nasopharynx and 28 *H. influenzae* strains from bronchial secretions were examined for their penicillin sensitivity. The growths of 31 of these respiratory strains were completely inhibited by 2.5 units of penicillin per c.cm. of medium. Only 7 strains showed growths on media containing 5 units of penicillin per c.cm., with evidence of marked inhibition.

The growths of 18 *H. influenzae* strains, 16 of which were of Pittman's Type b and all of which were isolated from the cerebrospinal fluid, were completely inhibited on medium containing 5 units of penicillin per c.cm. The growths of 16 strains were completely inhibited with 2.5 units of penicillin, the growths of 12 strains completely inhibited with 1 unit of penicillin, and only 3 strains completely inhibited with 0.5 unit of penicillin per c.cm. of medium.

It is suggested that penicillin therapy is worthy of trial in cases of *H. influenzae* meningitis.

Our thanks are due to Prof. J. W. McLeod for the supply of penicillin made available to him for experimental purposes by the M.R.C., and to Prof. W. J. Tulloch and Drs. J. M. Croll, J. S. Faulds, F. W. Gunz, A. I. Messer, G. McIntosh, K. Rogers, and C. J. Young for some of the meningeal strains of *H. influenzae* used.

MENINGITIS DUE TO A PENICILLIN- AND SULPHONAMIDE-SENSITIVE PITTMAN b STRAIN OF H. INFLUENZAE: RECOVERY

BY

D. G. McINTOSH, M.B., Ch.B., D.P.H.
Senior Assistant Medical Officer of Health, Dundee

AND

CONSTANCE F. DRYSDALE, M.B., Ch.B., B.Sc.
Senior Resident Medical Officer, King's Cross Hospital, Dundee

The following case appears to be of interest by reason of (1) the occurrence of *H. influenzae* meningitis during convalescence from meningococcal meningitis; (2) the isolation of a Pittman b type of organism which was sensitive to penicillin and sulphonamides (sulphamezathine and sulphathiazole); (3) complete recovery following treatment with penicillin and sulphamezathine.

Case Report

A female child aged 2½ years became suddenly ill on June 18 with vomiting and difficulty in walking. She was admitted next day to Dundee Royal Infirmary, where lumbar puncture revealed purulent fluid under increased pressure from which a pure culture of meningococci was obtained. In the course of three days while in the Infirmary she had been given 58,000 units of penicillin intrathecally and 10.5 g. of sulphadiazine by mouth, and was transferred to King's Cross (Infectious Diseases) Hospital, Dundee, on June 21.

On admission she was semicomatose and irritable. Pupils were equal and reacted to light (the left sluggishly). Kernig's sign was present; abdominal reflexes were absent. Temperature, pulse, and respirations were respectively 98.4° F., 144, and 32. Lumbar puncture revealed slightly turbid fluid under normal pressure. During June 21, 22, and 23 she received 18 g. of sulphamezathine by mouth and 75,000 units of penicillin intrathecally, and on June 23 lumbar puncture produced clear fluid under normal pressure; sugar was present. On June 24 the child's clinical condition appeared to be normal. It will be noted that for the meningococcal infection she had been given 133,000 units of penicillin intrathecally and 28.5 g. of sulphonamide (sulphadiazine 10.5 g., and sulphamezathine 18 g.) by mouth. On June 25 the evening temperature rose at 8 p.m. to 101° F. and the child became flushed and irritable, showing signs of upper respiratory catarrh—cough, injected conjunctivae, excessive lacrimation, congested buccal mucous membrane—suggestive of the invasive stage of measles, but Koplik's spots were not seen.

By June 27 marked neck rigidity had developed, Kernig's sign was present, muscular twitchings of the face and hands were observed, and lumbar puncture produced turbid fluid under increased pressure containing 35 cells per c.mm. and 75 mg. of protein per 100 c.cm. Sugar was absent. Numerous Gram-negative bacilli were demonstrated microscopically and a pure growth of *H. influenzae* (filamentous form) was reported by Prof. Tulloch. During the 7 days June 27 to July 3 the patient was given 75,000 units of Seitz-filtered penicillin intrathecally and 22 g. of sulphapyridine by mouth. On June 28 muscular twitchings were much less frequent, and next day had ceased. Improvement continued on July 1, 2, and 3, and on July 5 lumbar puncture revealed clear fluid under normal pressure; sugar was present. The evening temperature rose to 100.4° F. on July 6 and to 101.6° F. on the following evening, and a culture of *H. influenzae* was reported from the fluid obtained on July 5 and 7. During July 7, 8, and 9, 10 g. of sulphapyridine by mouth, 75,000 units of penicillin intrathecally, and 300,000 units of penicillin intramuscularly (12,500 units three-hourly) were given. On July 9 Prof. Tulloch reported that the organism was sensitive to penicillin (not so marked as standard staphylococcus), sulphamezathine, and sulphathiazole, but insensitive to sulphapyridine. Dr. Gordon, of Leeds, very kindly examined the culture, and reported that the organism possessed the characteristic colonial and serological features of a Pittman Type b.

In view of the bacteriological report sulphamezathine was substituted for sulphapyridine and during the 7 days July 10 to 16 22.5 g. were given by mouth. During the 9 days July 10 to 18, 175,000 units of penicillin were given intrathecally and 900,000 units intramuscularly (3-hourly injection). Apart from listlessness and the presence of intention tremors of the hands and forearms when picking up her toys, the child remained free from symptoms and her temperature became normal on July 8, on which day lumbar puncture revealed less turbid fluid, under normal pressure, containing 105 cells per c.mm. and 35 mg. of protein per 100 c.cm.: sugar was present: culture was sterile. On July 9 turbidity of fluid was less and cells numbered 20 per c.mm. Next day the fluid was clear, with sugar present and cells 5 per c.mm.: culture was sterile.

Cultures repeated on July 13, 15, and 23 were also sterile. Since treatment was restarted on July 7, 32.5 g. of sulphonamide by mouth (10 g. sulphapyridine, 22.5 g. sulphamezathine), 250,000 units of penicillin intrathecally, and 1,200,000 units of penicillin intramuscularly were administered. Details of daily dosages and of leucocyte counts are shown in the Chart, from which it will be seen that the standard intrathecal dose of 25,000 units of penicillin was increased to 50,000 units on July 11, 12, and 13. The injection on the last date gave rise immediately to the following symptoms:

As soon as the injection had been completed the child lay on her side with knees drawn up and uttering agonized cries continuously. Five minutes after the injection myoclonic movements of the face, arms, and lower limbs occurred, lasting about one minute. Five minutes later pallor, sweating, and vomiting occurred: the pulse rate was 125 per minute and the temperature 95.4° F. Gradual recovery took place over the course of 6 hours: 8 hours after the injection the temperature was 101° F. Next day the condition was normal, and recovery proceeded without interruption. The patient was discharged fully recovered on Aug. 16.

Discussion

An excellent review of the results obtained during the last five years in the treatment of meningitis due to *H. influenzae* has been given by Mutch (1941) and by Gordon, Woodcock, and Zinnemann (1944). In all but one (Jones and Sudds, 1942) of the references cited by the last-named authors serological examination of the causal organism had not been carried out. Gordon, Woodcock, and Zinnemann, following the suggestion of Mutch (1941), have examined serologically the organisms isolated from five cases. From two patients, aged 7 and 5 years, non-Pittman strains were isolated: both recovered after treatment with sulphapyridine (26 g. in 6 days and 21 g. in 7 days respectively). The other three cases were due to Pittman b strains. One of the patients, aged 5 years, recovered after three relapses, following the administration of 46.25 g. sulphapyridine. The remaining two were fatal: one of these patients, aged 5 years, died shortly after admission and before an adequate dosage of sulphathiazole could be given; the other, aged 2, died suddenly without specific treatment having been given, and the organism was obtained from a post-mortem specimen. Forgacs, Hutchinson, and Rewell (1945) described 2 cases, from both of which they recovered a penicillin- and sulphadiazine-sensitive Pittman b strain of *H. influenzae*. In their first case, aged 2½ years, striking improvement followed the intramuscular injection of 30,000 units of penicillin alone, and complete recovery resulted after giving about 210,000 units of penicillin intramuscularly and 36 g. of sulphadiazine within 7 days. The second patient, aged 1 year, died 10 hours after admission, having received approximately 12,000 units of penicillin and 2 g. of sulphamezathine. The prompt response observed in the present case after administration of penicillin and sulphapyridine was almost certainly due to the former, as the organism was found to be insensitive to the latter, although rapidly acquired drug resistance cannot be excluded, since sensitivity tests were not conducted until after relapse had occurred. The tendency for *H. influenzae* meningitis cases to relapse has been a feature of this infection. Archer and Singer (1943) reported the case of a child 5½ years of age who relapsed two days after receiving 30 g. of sulphapyridine in 10 days. Complete recovery followed the administration of 32 g. of sulphathiazole in 7 days. Birch (1943) treated a child of 3 years with 23.75 g. of sulphapyridine in 8½ days: 6 days after clinical recovery relapse took place. Permanent recovery followed the administration of 10 g. of sulphapyridine in 3½ days. One of the cases described by Gordon, Woodcock, and Zinnemann (1944), referred to above, relapsed on each of three occasions when sulphapyridine was withdrawn. Complete recovery ultimately ensued after 46.25 g. of the drug had been given. In the present case relapse occurred three days after cessation of treatment with sulphapyridine (22 g. in 7 days) and penicillin (75,000 units intrathecally in 3 days), followed by complete recovery after administration of 22.5 g. of sulphamezathine in 7 days, 1,200,000 units of penicillin (intramuscularly in 12 days. and 250,000 units of penicillin (intrathecally) in 7 days. This case endorses the recommendation of Forgacs, Hutchinson, and Rewell that cases of *H. influenzae* meningitis should be treated without delay with a combination of penicillin and a sulphonamide. In view of the high incidence of bacteriaemia (Mutch, 1941) combined systemic and intrathecal administration of penicillin is indicated. While sulphamezathine, sulphadiazine, or sulphathiazole is suitable for the beginning of treatment, sensitivity tests should be carried out with a series of sulphonamides in order that the most potent may be used, or another be held in reserve should relapse or drug sensitivity occur.

Summary

A case of *H. influenzae* meningitis which occurred during convalescence from meningococcal meningitis is described.

The organism belonged to the Pittman b type and was sensitive to penicillin, sulphamezathine, and sulphathiazole, but insensitive to sulphapyridine. Complete recovery followed treatment with penicillin and sulphamezathine in combination.

We desire to acknowledge our thanks to Prof. W. J. Tulloch for helpful advice; to Dr. J. Brodie, Lecturer in Bacteriology, University of St. Andrews, who carried out the bacteriological work; and to Dr. J. Gordon, Senior Lecturer in Bacteriology, University of Leeds, who typed the organism and to whom our notes of the case have been given for inclusion in his group of Pittman b type cases.

The report of the joint committee on the training and qualification of hospital administrators has been published as a pamphlet of sixteen pages by the Institute of Hospital Administrators, 12, Grosvenor Crescent, London, S.W.1. A representative conference held under the chairmanship of Sir William Goodenough in June, 1943, expressed the opinion that this branch of work is of such importance as to call for special training, leading to a recognized qualification, and that a standard qualifying examination should be established. The joint committee comprised representatives of Government Departments, the Association of Municipal Corporations, the British Hospitals Association, the County Councils Association, the Mental Hospitals Association, the L.C.C., and other interested bodies. The report includes among main recommendations that a standard examination in hospital administration common to all sections of the hospital service should be established; that it should be divided into two parts—intermediate and final; and that entry to the final examination should be restricted to persons with a minimum of two years' service on the administrative staff of a hospital.

(Neuropsychiatric Department, Royal Naval Barracks, Chatham)

The opportunity arose during July and August this year, at Royal Naval Barracks, Chatham, to examine a number (29) of ex-prisoners recently repatriated from Germany and referred to this department on account of neuropsychiatric symptoms. We therefore sought to obtain a clearer picture of the process of resettlement and of the "normal" reactions following repatriation. To do this we interviewed, in addition, an unselected group of 71 ex-prisoners who were apparently making a satisfactory readjustment, as judged by their not having reported any symptoms or difficulties. The 29 neuropsychiatric cases were referred as the result of routine medical examinations on their return to barracks after repatriation leave; the 71 unselected normals were referred through the co-operation of the officer appointed specially to care for the welfare of these men. As a general rule each man had completed a minimum of 42 days' leave; he was already assured of six months' shore service in this country and of special privileges in respect of extra week-end and night leave. Each rating was interviewed by this officer, and efforts were made to fit him into a suitable job and, wherever possible, to arrange for him to serve near his home. In the psychiatric interviews precautions were taken to avoid implanting doubts or the seeds of symptoms in men already adjusted or adjusting satisfactorily. These precautions imposed certain restrictions on the method of inquiry in the normal subjects—viz., a single interview and the avoidance of importunate questioning on intimate matters. Those abnormal cases which did not require admission to hospital were kept under observation and treated as out-patients. Within these limitations information has been sought on the incidence, clinical characteristics, and aetiological factors of neuropsychiatric disorders among these ex-prisoners and on the normal process of readjustment.

The case material has been divided into three groups: *Group A (71 cases)*, comprising men who were found to be making a good spontaneous readjustment with only trivial and transient difficulties, or none at all; *Group B (25 cases)*—men who showed minor neurotic reactions which, while they necessitated out-patient treatment and perhaps special recommendations for suitable employment, were not sufficiently disabling to prevent continuance at duty; and *Group C (4 cases)*—men who showed moderate or severe disorders necessitating admission to hospital or invaliding. These figures are quite unrepresentative of the incidence of neuropsychiatric disorders among repatriated naval ratings; more than 300 ex-prisoners passed through Chatham Barracks during July and August. It is probable that, with very few exceptions, all of those who showed moderate or severe disorders are included in the series. The great majority of those not referred for interview can be presumed to have found no serious difficulty, so far, in making a readjustment. Some of them may report sick later on, while a number of those included in Group B may, through the operation of hysterical mechanisms or adverse circumstances, later qualify for inclusion in Group C. It is too early to attempt to assess the influence which hysterical prolongation and elaboration may have upon the prognosis in these cases. Social and economic developments, as yet unpredictable, may play a decisive part.

Although no precise estimate of the incidence of neuropsychiatric disorder among naval repatriates can be drawn from our material, we have found no reason to believe that the incidence of severe disorders exceeds 5%. Using the ordinary prognostic criteria and assuming appropriate treatment, it seems likely that even in this group the proportion of men who will become problems for their lifetime is small. One of the four men included in Group C has already been discharged from hospital fully recovered after eight weeks' treatment.

Group A.—The Normal Reaction (71 Cases)

Thirty of these men said that they had not at any time since their repatriation experienced any difficulty at all in resuming relations with their families and friends or in adapting themselves to life at home, on leave, or afterwards at duty in the barracks. A typical comment on the home-coming was: "It was just like going back for an ordinary leave." The existence of this group is perhaps one of the most sociologically important and encouraging facts that have emerged from this investigation. These men left an impression of a positive drive towards a successful readjustment, and of a resilience and a resource which, in our opinion, justify a firm confidence in their stability.

The remaining 41 men admitted having experienced difficulties at first which, although not always trivial, were transient, devoid of neurotic overvaluation, and no longer caused any serious trouble at the time of their examination. We would agree with Newman (1945) in holding that "these are not neurotic or psychopathic phenomena, but a normal response of a normal man to release from an abnormal external environment."

The commonest of the phenomena of readjustment shown by our subjects are given below in order of frequency. They persisted for periods varying from a few days to two months; two weeks was commonly given as the duration.

1. Restlessness, inability to settle to any one activity for any length of time.—This very common experience often included difficulty in concentrating on intellectual activities, such as reading or writing letters.
2. Impatience and irritability.—A few said that they had found themselves too exacting, others that they had been "on edge"; one said he was "like a cat on hot bricks," two others that they were "fed up with being asked questions." Waiting in shopping and bus queues was found particularly exasperating and in a few cases provoked a "cold sweat."
3. Difficulty in mixing and entering into conversation with relatives and friends owing to lack of common topics.—A few found difficulty in becoming interested in topics outside their own experience. A few were self-conscious; one felt tongue-tied in the company of women, and another was afraid of lapsing into bad habits—e.g., swearing. Many preferred to stay indoors for the first few days.
4. Dyspepsia and diarrhoea.—This appeared in some cases to have been a physiological reaction to over-indulgence in food and drink immediately after repatriation.
5. Insomnia, usually over a very short period.

One man mentioned that he had been afraid to cross the road, another that he had on two occasions almost been knocked down by a motor-car in a busy street. Yet another became seriously alarmed when the trains in which he travelled entered a tunnel. A normally thrifty man spent his money "like water" until his relatives took him in hand. Finally, one man said he had had no difficulty in settling down once "everybody stopped trying to do everything for me all at the same time." Inability to express themselves more clearly led a few to confine their remarks to saying that they had "felt strange" for a few days. Not one of these phenomena is specific to ex-prisoners of war; they might be shared by anyone returning home after a long absence.

Antisocial traits leading to resentment of authority and to indiscipline have so far not been a serious problem. Minor leave-breaking has occurred from time to time, but graver offences have been rare. The chronic offender who has always been a "King's hard bargain" seems to be neither more nor less of a Service and social problem than he was before his captivity. A striking negative finding has been the absence of complaints of sexual difficulties. Making due allowance for reticence, it is remarkable that not one of these 71 men made any complaint on this score. Inquiry into their experiences and behaviour leads us to believe that the great majority achieved a compromise solution of this problem during captivity which did not give rise to any serious difficulties afterwards. The overwhelming majority seemed to have found hunger far more important than sex-deprivation, and observed that conversation on sexual matters and sexual unrest were mainly confined to the short periods after the arrival of Red Cross parcels, when hunger was temporarily appeased.

It may perhaps be mentioned here as illustrating their fundamental stability that some of these men who achieved a rapid spontaneous readjustment did so in the face of great domestic misfortune. One very stable man whose wife had an illegitimate baby six weeks after he returned home had, after a struggle with himself, decided to forgive his wife and to bring up the child with his own son. This man had been a prisoner for three years. His attitude had already become tolerant and reasonable. His only complaint was of nausea and anorexia, which he attributed to over-indulgence in food and drink during his first week at home. Another man had learned of his wife's infidelity nine months before he was repatriated, and became restless and unable to sleep without drugs until he came home. He still found it hard to forgive his wife, but his insomnia had cleared up within six weeks of his return.

Most of the men were not aware of any change in their character or mental outlook and said that none had been noticed by their relatives. A dozen thought there was some slight change; but, so far from this being in the general direction of impairment, all but a few who considered, for example, that they had become "harder," felt that the change was for the better—e.g., "wiser," "more serious," "broader in outlook." Here again some, for lack of capacity for self-expression, found difficulty in describing the change save as "older" in the sense of more mature. The observation of Charters (1945), based on his experience with severely wounded prisoners, applies in some degree to many in this group: "Rather would I say that the majority of these men have gained in tolerance, understanding, patience, forbearance, and courage. They have acquired a bigger concept of comradeship, and of community life. They have more fully recognized the need for the individual to pull his weight in the interest of the group."

Groups B and C.—Abnormal Reactions (29 Cases)

Twenty-nine men complained of psychiatric or psychosomatic symptoms at the time they were examined. The diagnoses made were as follows:

Anxiety state	18 cases
Anxiety state with hysterical features	3 „
Anxiety state with mental backwardness	1 case
Hysteria	2 cases
Reactive depression	3 „
Migraine	1 case
Post-concussional state	1 „

In 17 of these cases the onset of symptoms occurred during captivity, in 12 after repatriation. Four (Group C) were severe enough to need admission to hospital. The remainder (Group B) were treated as out-patients while still at duty; segregation in a rehabilitation centre was unnecessary, and, in any case, appeared to hold out less promise of success than a gradual and careful reintroduction to normal duties.

Except in four cases (Group C), the symptoms and signs were seldom very disabling or severe, and usually responded satisfactorily to simple methods of explanation, reassurance, sedation, and psychological management. Often the symptoms complained of differed only in their greater intensity or persistence from the phenomena previously described as normal. It is legitimate to ask, Would these so-called abnormals have made a successful adjustment given a little longer in which to achieve it? It is hoped that our reasons for regarding these cases as neurotic will be apparent in the brief descriptions which follow. Some of these men would probably have made a complete recovery sooner or later without any special treatment, others might never have asked for medical help had they been able to continue their efforts to readjust at a slower tempo in their own homes. However liberally leave may be granted and Service rules interpreted, returning to duty, with its unwelcome separation from home, the inevitable mixing with a crowd of strangers, and the obligation to conform with an impersonal code of behaviour, is an ordeal for the repatriated prisoner. Help in facing up to this ordeal was what many of these men required.

Selected Case Summaries

Case 1: Group C.—Able seaman aged 27; C.S.* Date of capture, June, 1942. Joined the Navy in 1933. Strong family history of psychosis. Previously stable and healthy apart from slight unilateral deafness. Very nervous during the action which led to the sinking of his ship and to his capture. Sustained splinter wounds of the neck and leg during this action. During captivity, after five weeks in hospital for his wounds, he had "influenza" three times; he complained of frequent "blackouts" while short of food in Italy, and of tinnitus dating from the final action. In Jan., 1945, his camp was evacuated owing to the Russian advance, and he began a march which lasted four months. The columns were attacked on two occasions by Allied planes and many men were killed or wounded. The stress was very severe and there was panic. On his return home he found his wife in bad health, having been invalided a year before from the W.R.N.S. He found it difficult to settle down at first, and "kept looking round to see if anyone was following with a rifle." He preferred to be alone, and would leave the room if anyone came in. On waking he had difficulty in realizing that he was not still a prisoner. He complained of bad dreams and of twitching of the face. On examination—after leave:—Intelligence normal; nutrition good; marked tremor; increased tendon reflexes; facial tics; blood pressure 150/105. Diagnosis:—Anxiety state. Main precipitating factors: experiences on the long march shortly before repatriation, and discovery of his wife's ill-health on return. Admitted to hospital and later invalided on grounds of aural and psychiatric disabilities.

Case 2: Group B.—Stoker aged 27; C.S. Captured Jan., 1942. Joined the Navy in 1938. Previously healthy and stable; keen on games and athletics. Considerable stress in previous actions (ship sunk). During the action which led to his capture he was wounded in the right knee and had to swim around for ten minutes before being picked up by a German trawler. Throughout his captivity he was afraid to do anything strenuous lest his knee, which gave continual trouble, should be permanently crippled. Thus he became a reluctant spectator of the games and other physical activities which he had formerly enjoyed. This enforced inactivity preoccupied his mind and became the dominant factor in his life. Shortly before his release he became very nervous after Allied bombing of his camp, which resulted in a number of casualties. At the end of his leave he reported sick because his "mind seemed to wander off." He had found that his attention often lapsed during conversation, and he would "come to" to find that his companion had broken off the conversation and was walking away. On examination:—Intelligence normal; nutrition fair; no physical signs of anxiety. He was mildly depressed, concerned about his lapses of attention, but in other respects showed a certain apathy, indifference, and loss of initiative and vitality in both physical and mental spheres, which he expressed as, "It's taken the stuffing out of me." Diagnosis:—Mild reactive depression. Main precipitating factor: enforced inactivity. Improved with reassurance, but prognosis uncertain for complete recovery.

Case 3: Group B.—Signalman aged 25; H.O.* Captured May, 1941. Joined the Navy in Aug., 1940. Previously healthy and stable. Considerable stress in earlier actions. In the action which led to his capture his ship was sunk with the loss of hundreds of lives. He remained well for the first two years of his captivity, then developed anxiety symptoms after Allied bombing of the camp area which resulted in 30 deaths. Subsequently was excused work on many days on account of headaches. "Something snapped in my brain." During the period after release while awaiting repatriation he developed a fairly severe psoriasis (his first attack), which cleared up after he was admitted to hospital while on repatriation leave. After leave he reported sick, complaining of apprehensiveness, self-consciousness, anorexia, and epigastric discomfort. He was chiefly concerned, however, over the fact that during leave he had been capable of intercourse with his wife only twice a week. He was 2 st. under weight on return home and had regained this during leave. He had married only nine months before he was captured; he admitted to having masturbated "nearly every night" while in captivity, and felt guilty about it. On examination:—Intelligence normal; nutrition good; no physical signs of anxiety. He had not expected to be called on to continue to serve in the Navy. The personality was hysterical; he exhibited much self-pity and a poor morale. Diagnosis:—Anxiety state with hysterical features. Main precipitating factors: stress at time of capture, bombing during captivity, worry over marital relations, the whole coloured by deficient morale.

Taking these groups of 29 cases as a whole the symptoms most often met were irritability, nervousness, gastro-intestinal disturbance, insomnia, restlessness, dislike of mixing in crowds, excessive sweating, tremulousness, self-consciousness, nightmares, headaches, and a feeling of being out of touch. Many other symptoms—e.g., listlessness, difficulty in concentration, intolerance of noise, "blackouts"—were only slightly less common. The frequent occurrence of psychosomatic complaints—nausea, anorexia, diarrhoea, excessive sweating, tremulousness—was striking. Tachycardia and tremor were common physical signs, but, except in the case of one man with early mitral stenosis, effort syndrome was not seen.

---

* C.S.=Regular naval ratings. H.O.=Ratings serving for the duration of hostilities only.

As to character and mental outlook, a number of these men reported slight changes in the direction of increased tolerance and maturity similar to those met with in Group A. The problem is complicated by the persistence at the time of examination of symptoms, such as irritability, which may or may not prove to be permanent. There was in some cases an impairment of morale which may influence the prognosis with respect to readjustment to Service life. With this proviso, however, the outlook for ultimately successful readjustment, at any rate as civilians, appeared in most cases to be good.

Aetiological Factors: 1. Factors operating Before Captivity

These hundred men belonged to many branches of the Royal Navy—seamen, engine-room, and special branches—and differed in non-commissioned rating, age, experience, and background. They represent, in fact, a cross-section of the whole, and could hardly have been a better illustrative sample had they been the result of deliberate choice. Perhaps these points can best be shown in tabular form, although any conclusions which may be drawn from such small numbers can only be regarded as lending weight to clinical findings.

Table I.—*Service Background*

	Group A (Normal Reaction) 71 Cases		Groups B and C (Abnormal Reaction) 29 Cases	
	No.	%	No.	%
Total number of N.C.O.s ..	18	25	9	31
Total number below N.C.O. rank	53	75	20	69
Ratings serving for hostilities:				
Volunteers	15	29	7	24
Conscripts	29	41	8	28
Ratings in continuous service ..	23	32	13	45
Reservist ratings	4	6	1	3
Length of service in R.N. before capture:				
Two years or less	48	68	16	55
Three, four, or five years .	8	11	5	17
More than five years.. ..	15	21	8	28
Ages (Aug., 1945):				
27 and under	37	52	20	69
28 and over	34	48	9	31
"Age-and-service groups" for demobilization:				
30 and under	25	35	12	41
31 and over	29	41	8	28
Regular naval ratings with further service	17	24	9	31

Table I shows that abnormal reactions are fairly evenly distributed among all types of rating and are not predominant in any one group of men. An exception is a higher percentage of younger men in the abnormal groups, B and C. These men were captured from ships or in actions in widely different situations and circumstances. Such names as Crete, Normandy, Coastal Forces, Malta Convoys, Submarines, Dieppe, Saint-Nazaire, and Spitzbergen are examples which illustrate their varied service; there is even one parachutist among them.

Table II.—*Experience of Action Stress*

	Group A (71 Cases)		Groups B and C (29 Cases)	
	No.	%	No.	%
A history of previous action and severe war stress in the Navy	35	49	16	55
Severe stress at time of capture	71	100	28	96
Many shipmates killed in action at time of capture	42	59	17	59
History of bad reaction to stress in action at or before capture	1	1	4	14

A glance at Table II shows that the amount of stress of this kind is almost evenly shared between the two groups. It is here, however, that the first striking difference can be noted. Although the totals are very small, a higher proportion of those who show abnormal reactions on release reacted badly to action stress.

This difference is again apparent when the personal histories of these ratings are considered. Here, also, each figure in itself is small, but the total of evidence is in favour of a higher proportion of those with a neurotic predisposition in Groups B and C.

Table III.—*Personal Histories*

	Group A (71 Cases)		Groups B and C (29 Cases)	
	No.	%	No.	%
Family history showing two or more near relations with psychiatric disorder	2	3	6	21
Illegitimate birth	1	1	1	3
Loss of both parents in childhood ..	4	6	1	3
Loss of one or other parent in childhood	7	10	4	14
Neurotic traits in early childhood ..	0	0	5	17
A poor school record (Standard V or below)	0	0	2	7
Unstable work record	3	4	3	10
Serious physical illness in the past ..	1	1	1	3
Neurotic breakdown in the past	1	1	2	7
Evidence of marked personality defect ..	2	3	7	24
Married or engaged before capture ..	32	45	12	41
Single	39	55	17	59

2. Factors operating During Captivity

The men were confined in many different camps in Italy and Germany, a large proportion of them in either Marlag M or Stalag 8b (Lamsdorf). Many of the lower ratings were given arduous forced work by the Germans. A few managed to avoid it, usually from patriotic motives, but a small number preferred to occupy their time in this manner; ratings of N.C.O. standing were not liable for forced labour. Neurotic reactions on release were a little more frequent in those who had done forced work. Nearly all were very badly fed, and most of them lost a considerable amount of weight. Red Cross parcels were all-important, and in periods without them suffering was greatly increased. Exposure to physical cruelty by their captors and exceptional privation (save during the final march) were very rare and almost confined to Group A. Large numbers, however, were on the march for anything from a fortnight to four months in the early months of 1945. This was exceptionally rigorous, and in some cases they were exposed to bombing and shooting by our planes, which killed some of their companions. Again, a few were bombed in factories or in their camps earlier in captivity. Neurotic reactions were more frequent in men exposed to these hardships and dangers, and several ascribed anxiety symptoms to such experiences. Physical illness was not uncommon, and was more frequent in Groups B and C. Some also had been wounded on capture. Neurotic illness during captivity was not recorded in Group A and was rare in Groups B and C.

The length of captivity varied between nine months and five and a quarter years, the greatest number—42—being in captivity for three years. Neurotic reactions were somewhat more common in those who had been imprisoned for more than three years. (Of the men captive for more than three and less than four years, 22 in Group A and 10 in Groups B and C were from the same ship, a destroyer, in which, incidentally, morale had been extremely high.)

Finally, among the factors operating during captivity, the recreation and activities of these ratings were studied. Forced labour did not leave time or energy for much activity, nor did insufficiency of food help matters. It is true that a higher proportion of abnormal reactions was found in those who did not occupy themselves, but it is difficult to assess whether this was *post hoc* or *propter hoc.*

It seems to be apparent from Table IV that although the stresses of captivity, such as greater duration, forced labour, and physical illness, were more frequent among those who subsequently developed neurosis, these differences are on the whole small. In fact, in contradistinction to the prophecies of some writers, neurotic predisposition as shown in Table III appears to be of somewhat greater importance than the stresses of captivity. It should, however, be mentioned that among the 30 men in Group A who experienced no difficulties at all during the period of readjustment the proportion who had been subjected to severe stress in action before the incident which led to capture was less than in any other group. During captivity proportionally fewer of these men lost weight, were exposed to bombing or gunfire, or suffered from physical illnesses.

The return in the near future of many men who have been in Japanese hands may throw greater significance—in their case at least—on those factors operating during captivity. It remains to be seen what will be the effect of this latest example of man's inhumanity to man.

TABLE IV.—*Factors operating during Captivity*

	Group A (71 Cases)		Groups B and C (29 Cases)	
	No.	%	No.	%
Captured by Germans	39	55	17	59
Captured by Italians and later in German hands	32	45	12	41
Wounded at capture	15	21	5	17
Average duration of captivity	2·8 years		3·2 years	
Forced labour	39	55	21	72
Loss of weight during captivity	54	76	24	83
Admitted sex difficulties during captivity	2	3	5	17
Bombed in camp or on the march	34	48	17	59
Long march lasting 2 weeks to 4 months, early 1945	42	59	20	69
Other stress:				
In open boat for some days after ship sank Beaten up by S.S. men Chained for a long period Exceptional privation	9	13	2	7
Physical illness during captivity	24	34	15	52
Neurotic „ „ „	0	0	3	10
Domestic stress at home during captivity (death of near relative, etc.)	5	7	1	3
Recreation (physical):				
Active (played games, etc.)	49	69	11	38
Inactive (watched games, etc.)	17	24	13	45
None	5	7	5	17
Recreation (intellectual):				
Active (constructive study, etc.)	24	34	9	31
Inactive (light reading, etc.)	40	59	14	48
None	5	7	6	21

3. Factors operating after Repatriation

The very successful and greatly appreciated policy of repatriating these men by air entailed an extremely rapid transition from captivity, danger, and privation, and implied that the demand for readjustment came with startling suddenness. Their arrival was in most cases to happy homes. Difficulties and even tragedies were bound to occur in a few cases, and it was found that the incidence of serious domestic misfortune after return was 6% in Group A and 10% in Groups B and C. It certainly accounted in part for the onset of symptoms in a very small number. To offset this preponderance of domestic misfortunes in Groups B and C there was also a higher incidence of long-awaited marriages and new engagements in these groups.

In addition, the circumstances to which these men were called upon to adapt themselves on repatriation varied according to their status in the Navy. Some of the regular naval ratings had several years still to serve; others were nearing or had already passed their pension date, and could expect early release. Those who were "Hostilities only" ratings were scheduled in age-and-service groups (see Table I) for release within varied periods of time. In general they showed a willingness to carry out their contract, though it was noticeable that some of the more senior ratings who had previously been keen and ambitious in their naval careers had lost their enthusiasm. While prepared to serve out their time, they looked forward eagerly to the day when they could settle down at home in a "quiet job."

It is of importance that these repatriated men have come back to a victorious country, with the hope of taking up the threads of their lives again apparently to be fulfilled. The optimism induced by this has hardly been damped by the austerity of life in this country, although many were surprised at the sparseness of rations and the emptiness of the shops. It is yet too early for the full effects of the difficulties of a post-war world to make themselves felt. Again, a sweeping Labour majority may have added to their hopes of better social conditions. The influence of these factors cannot be discounted when the low incidence of neurosis is considered.

Summary

In a series of 100 naval ex-prisoners of war, examined two to three months after repatriation, the incidence of severe neurotic reactions was very low. An encouragingly large proportion had no difficulty at all in achieving a successful readjustment within this period of time. Neurotic reactions, usually of no great intensity, occurred in a minority of the cases. The symptomatology comprised nearly all the characteristics common to the minor affective disorders of Service and civilian practice, and was distinguished by the frequent occurrence of psychosomatic complaints and of restlessness and irritability. The tendency was for these symptoms to respond fairly quickly to simple methods of treatment and management. While psychogenic factors operating before, during, and after captivity all played their part in precipitating neurotic reactions, constitutional predisposition was found, on the whole, to have been more important. This finding does not exclude the possibility that where there are greater environmental stresses, as may prove to have been the case among prisoners in Japanese hands, these may gain greatly in importance.

We wish to express our thanks to Surg. Capt. Desmond Curran, R.N.V.R., and Surg. Cmdr. J. A. Fraser-Roberts, R.N.V.R., for advice on the presentation of the results of this inquiry.

SIXTH-NERVE PARALYSIS AFTER SPINAL ANALGESIA

BY

W. A. FAIRCLOUGH, M.B., F.R.A.C.S.

Ophthalmic Surgeon, Auckland Hospital, New Zealand

Analgesia by spinal injection was first practised about the beginning of the century. The pioneers used cocaine or cocaine and adrenaline for induction, but owing to the frequency of toxic after-results the method fell into disuse for a time. The introduction of stovaine soon followed, giving the procedure a new stimulus, and it was adopted by surgeons throughout the world.

The early workers reported paralysis of the eye muscles as a rare complication. Tuffier (1905–6), having used this method in 2,000 cases, gave it as his opinion that no bad results followed spinal analgesia. General experience since that time calls for some revision of his opinion, because, in addition to other unfavourable results, paralysis of the cranial nerves has occurred in hundreds of cases after spinal injection, and of the 12 nerves only the olfactory, glossopharyngeal, and vagus have escaped (Hayman and Wood, 1942). However, of all these cranial paralyses well over 90% involve the abducens. The incidence (Hayman and Wood, 1942) of abducens paralyses after spinal injection was given by Terrien in 1923 as one in 100; by Contonnet and François in 1933 as one in 250. Experience here (1944) indicates that it occurs once in 202 cases.

During the last ten years the literature on the subject has been sparse, and the number of cases reported comparatively small. Hayman and Wood (1942) discuss the subject and publish two cases. The paucity of records of late years may be due to improvement in technique and drugs, or possibly to lack of interest in the subject. Whatever the cause, the fact remains that during the last two years, since making inquiries about the condition, 10 cases of sixth-nerve paralysis after spinal analgesia have been referred to me.

The abducens is notoriously vulnerable in cerebral lesions and increased intracranial pressure generally. The various theories that have been advanced to account for this susceptibility of the sixth nerve to injury are:

1. That the long course of the nerve exposes it to injury. Incidentally the trochlear (fourth) is the most slender cranial nerve, and it has the longest intracranial course—about 75 mm.

2. Cushing's opinion that the nerve may be damaged between the pons and occipital bone at the site where the anterior inferior cerebellar artery crosses it anteriorly at right angles, as it does in over 80% of normals. The internal auditory artery is also credited with injuring the nerve in the same way.

3. That the nerve may be injured where it bends over the angular apex of the petrous bone. As in increased intracranial pressure, the brain in some cases may be forced down into the foramen magnum, and the sixth nerve, being practically fixed at its two ends, in the pons and cavernous sinus, becomes stretched and is damaged as it bends over the more or less sharp petrous angle.

The following theory, though not providing the basal cause of paralysis of the sixth nerve, would account for the fact that it so often shows signs of injury earlier than any of the other cranial nerves, and that it may do so even if its anatomical disadvantages did not exist.

A New Theory as to the Cause

In intracranial conditions, toxaemias, mechanical disturbances, and inflammations all the cranial contents are influenced by the disturbing factor, and frequently there comes a time when the abducens shows clinical signs of being affected—the first nerve to show evidence of trauma. I submit some points concerning binocular vision and the necessary faculties concerned in its maintenance that seem to be definite contributing factors in causing the abducens to be so often the earliest cranial nerve to supply clinical evidence of cerebral pathology.

It is well recognized that the highest and most recently acquired faculties and attributes of the human being are the first to be lost or disturbed under stress. A patient undergoing general inhalational anaesthesia without premedication is the common illustration of the fact. From a phylogenetic point of view, binocular stereoscopic single vision—characteristic of the primates only—is one of these latest-acquired attributes. Binocular vision (Duke-Elder, 1932) is a single mental impression, brought about by the co-ordinate use of the two eyes. To maintain it it is necessary (1) that the two fields of vision overlap; (2) that the corresponding points of each retina function together; (3) that the cerebral fusion-sense functions; (4) that the synergic action of the extraocular muscles is such that the three previous conditions can function.

Ample evidence of defects in the last three conditions necessary to maintain binocular vision is very prevalent. Non-correspondence of retinal points, the dominant eye, and defective fusion sense are of frequent occurrence. Eye-muscle imbalance and insufficiencies, concomitant squint, the heterophorias or latent squints, and refraction errors all have a definite bearing on the subject, and are so common as to affect a considerable proportion of the population. The eye examinations of candidates for fitness for flying have revealed the frequency of defects in the binocular vision system among seemingly normal young men.

A study of the evolution and physiology of vision in general encourages one to appreciate how the injection of a toxic drug into the central nervous system could probably cause diplopia. The whole visual faculty and the brain are so essentially interdependent that the late Prof. Elliot Smith stated that the cultivation of vision acted as a powerful stimulus in the development of the cerebral hemispheres, and that vision is the fundamental factor in the development of the cerebral cortex and intelligence of the human type.

The varying stability of the binocular vision function makes it possible that any cerebral pathology, even slight in degree, would tend to cause a breakdown of the binocular system, with resulting diplopia. A person more or less under the influence of alcohol first loses his highest and latest-acquired attributes—reason, judgment, fine co-ordination, and binocular single vision. Only some have or retain the wit to be aware of the double vision, but it is commonly present if looked for. A partially inebriated man, when reading, often unconsciously closes one eye to avoid confusing the images. This type of diplopia is generally uncrossed and lateral—that is, an abducens defect is present. It seems unnecessary to assume that this double vision is due to the alleged intracranial anatomical disabilities of the sixth nerve. Some other factor causes diplopia, and I suggest that the common presence of a defect in one or more of the above essentials necessary for the maintenance of binocular vision, and an added toxin, together provide the factors causing the abducens to falter or fail in its function.

It is not uncommon for patients with certain muscle insufficiencies to complain of occasional diplopia, and to mention that they quite often read with one eye closed more comfortably than with the two eyes open. This is due to the difficulty they have in maintaining binocular vision—without any toxic drug. By closing one eye the single binocular vision effort is abandoned, and the covered eye wanders from the correct alignment.

In none of the 10 cases of diplopia here recorded was the paralysis complete. In some it was slight and in others marked, but all retained some power of abduction. The complete sixth-nerve paralysis following skull fracture or certain other cerebral lesions is a quite different clinical entity. It is probable that a toxic drug acting on an unstable binocular vision function is in many cases the cause of the diplopia and abducens paralysis following spinal analgesia.

Normally the adduction power of the two eyes is three times that of abduction, measured in prism dioptres. Esophoria is a common form of muscle imbalance. It is a latent convergent squint. To prevent the latent squint becoming obvious or manifest an extra tonic nerve impulse is constantly sent by the abducens to the external rectus of each eye to preserve parallelism of the eyes and avoid diplopia. If a spinal injection is given to a patient with esophoria, where the tonic contraction of both external rectus muscles is present in order to overcome the tendency to convergent squint, only a slight trauma of the abducens would block this extra tonic impulse which is required to maintain parallelism of the eyes, and the esophoria or latent squint would then become a manifest convergent squint with uncrossed double vision. Further, no theory that I am aware of has been put forward to account for the abducens paralysis being so commonly unilateral and only partial. That it is so may be explained by the probability that in esophoria, when diplopia is established and the extra impulse required to maintain binocular vision has been abandoned, the second eye is often able to carry on monocular movements normally with the less-powerful stimulus.

Defects of the other previously mentioned component parts of the binocular system may also offer reasonable explanations of the frequent early production of diplopia. Examination of these functions before and after spinal injection may prove of interest. Of the 10 cases here reported 9 were examined after the patients considered that their eye condition had returned to normal. Each of them had some degree of esophoria varying from 1 to 5 P.D. at 6 metres, and none had exophoria.

Other Causal Theories

Various authorities hold different theories—some being directly opposed to others—regarding the cause of abducens paralysis following spinal injection. None take any note of the possibility of an unstable binocular vision function entering into the picture, and none of these opinions explain the great preponderance of unilateral paralysis.

These causal theories (Hayman and Wood, 1942) may be grouped under three headings:

1. Mechanical Causes.—One argument for this theory gains support from the fact that paralysis of the sixth nerve has followed ordinary spinal puncture without injection. Some suppose there is a pre-existing hypertensive condition of the cerebrospinal fluid, and the added injection provides the last straw, as it were. Others think the palsy is due to hypotension of the fluid from continued leaking after the puncture.
2. Toxic causes, relating chiefly to the drugs used.
3. Inflammatory Causes.—Supporters of this idea suppose a low-grade meningitis is set up by organisms of low toxicity, and they consider that ocular paralyses following the introduction of air into the ventricles uphold the theory. Hayman and Wood believe that the problem will be solved on the basis of a disturbance in the dynamics of the spinal fluid during spinal analgesia.

The common symptoms following lumbar analgesia are headache, pain in the neck, dizziness, photophobia—the latter two symptoms may be due to threatening or partial diplopia—and diplopia. Though the abducens paresis may be partial, the convergent squint and limited outward movement of the eye are easily demonstrated. Homonymous diplopia is present, the distance between the images increasing as the test object is moved into the sphere of action of the paralysed muscle; secondary deviation can be seen, and false orientation can be demonstrated by covering the unaffected eye. The headache appeared in the present cases between the second and fourth days, and had faded away in between five days and five weeks, except Case 2, in which the headache persisted for about fifteen months. The diplopia appeared five to eleven days after the spinal injection, and persisted for varying periods—1, 2, 3, 4, 5, 6 (2) weeks, 2 months, 3 months, and 14 months. Relief from headache and diplopia occurs gradually.

The prognosis is therefore ultimately good, though occasionally the complications may reactivate existing neuropathic conditions which may prove fatal (Blatt: quoted by Hayman and Wood, 1942).

Treatment

Sedative drugs are not very effective in treating the severe basal and general headaches, but keeping the head in the horizontal position gives some relief. The inhalation of oxygen, using the B.L.B. inhaler, has given definite relief in many cases. Galvanism for the paresis is of psychological value only.

For the diplopia, covering the deviating eye gives relief, but continued covering is not advised, as thereby any subconscious effort to fuse images and re-establish binocular vision will not be made. Dark glasses should be worn, with the outer third of the glass before the affected eye made opaque with, say, adhesive black paper. It is probable that muscle exercises and fusion-training may assist in re-establishing parallelism of the eyes and binocular vision in cases in which natural recovery is delayed.

Case Reports

Case 1.—Mrs. A., aged 36. Uterine operation, April 20, 1943—Mr. Douglas Robb. Spinal percaine 1/200, 1.5 c.cm. The patient suffered from bronchiectasis and was unfit physically. She became pregnant, and it was considered advisable to terminate the pregnancy. Headache appeared on the second day and persisted for three weeks. Diplopia was complained of on the fifth day after the lumbar injection and persisted for five weeks. The right abducens was paretic; a certain degree of abduction of the eye was possible. Homonymous diplopia, increasing to the right, and all the signs of paralytic strabismus were present. Two months later the patient felt completely well so far as the eyes were concerned, though she still showed 5 P.D. of esophoria. Probably this is her usual state of muscle imbalance. Right vision 6/6, Hm. 0.50; left vision 6/6, Hm. 0.50; fundi normal. This patient was in the habit of "standing" on her head and shoulders three times a day for about half an hour at a time in order to empty the bronchiectatic cavities. While in this position she constantly noted an easing of the headache and that the double vision seemed less marked. This statement suggests several possibilities. One of the male patients was later prescribed standing on the head and shoulders for a quarter of an hour three times a day as treatment. He reported no benefit.

Case 2.—Miss B., aged 22. Appendicectomy, April 20, 1943—Mr. D. W. Guthrie. Spinal percaine 1/200, 2 c.cm. Headache appeared on the third day and persisted for 15 months. Diplopia was complained of on the seventh day and persisted for about 14 months. The right abducens was partially paralysed, with all typical signs. April, 1944—a year later: The headache persisted, with occasional diplopia; 12 P.D. of esophoria with Maddox rod and tangent scale. Aug., 1944: Occasional headaches, but no diplopia; 5 P.D. esophoria present; right vision 6/6, no Hm.; left vision 6/6, no Hm.; fundi normal.

Case 3.—Mr. C., aged 40. Haemorrhoidectomy, Sept. 14, 1943—Mr. F. P. Furkert. Spinal percaine 1/200, 1.5 c.cm. Headache appeared on the third day and persisted for three weeks. Diplopia was complained of on the seventh day and persisted for three months. Right abducens partial paralysis was present with all typical signs. This patient tried standing on his head for 15 minutes three times a day without benefit. Sept. 27, 1944: Esophoria 2-3 P.D. present; slight congenital ptosis right eye; right vision 6/18, anterior polar cataract; left vision 6/6 with 1. cyl. vert.; fundi normal.

Case 4.—Mr. D., aged 65. Cholecystectomy, Dec. 19, 1943—Mr. D. W. Guthrie. Spinal percaine 1/200, 3 c.cm. Headache appeared on second day and persisted for two weeks. Diplopia was complained of on the eighth day and persisted for six weeks. Left abducens affected. Oct. 19, 1944: Esophoria 1 P.D.; right vision 6/6, Hm. 25; left vision 6/6, Hm. 25; fundi normal.

Case 5.—Mrs. E., aged 38. Cholecystectomy, May 22, 1944—Mr. D. W. Guthrie. Spinal percaine 1/200, 2.5 c.cm. Headache appeared on the fourth day and persisted for 10 days. Diplopia was complained of on the fifth day and persisted for three weeks. Right abducens paralysis. Aug. 8, 1944: Esophoria 3 P.D.; right vision 6/6, Hm. 0.75; left vision 6/6, Hm. 0.75; fundi and fields normal.

Case 6.—Mrs. F., aged 35. Appendicectomy, June 6, 1944—Mr. J. Fitzsimons. Spinal percaine 1/200, 2 c.cm. Headache appeared the second day and persisted for eight days. Diplopia was complained of on the sixth day and persisted for four weeks. Right abducens paralysis. Oct. 3, 1944: Esophoria, 1 P.D.; right vision 6/6, Hm. 50; left vision 6/6, Hm. 50; fundi normal.

Case 7.—Mr. G., aged 47. Haemorrhoidectomy, Aug. 15, 1944—Mr. J. Dreadon. Spinal percaine 1/200, 1.5 c.cm. Headache appeared on the second day and persisted for two weeks; diplopia complained of on the eleventh day and persisted for two months. Right abducens paralysis. Oct. 20, 1944: Esophoria 2 P.D.; right vision 6/6; left vision 6/6; fundi normal.

Case 8.—Mr. H., aged 57. Right inguinal herniorrhaphy, Aug. 18, 1944—Mr. A. Smith-Gray. Spinal percaine 1/200, 2 c.cm. Headache appeared on the third day and persisted for three weeks. Diplopia was complained of on the seventh day and persisted for six weeks. Right abducens paretic.

Case 9.—Mrs. I., aged 50. Operation for stone in common bile duct, Aug. 29, 1944—Mr. J. Fitzsimons. Spinal percaine 1/200, 2.5 c.cm. Headache appeared on the second day and persisted five weeks. Diplopia was complained of on the fifth day and persisted for six weeks. Left abducens paralysis. Oct. 18, 1944: Esophoria 1 P.D.; right vision 6/6, Hm. 1; left vision 6/6, Hm. 1; fundi normal.

Case 10.—Mrs. J., aged 46. Cholecystectomy, Oct. 2, 1944—Mr. D. W. Guthrie. Spinal percaine 1/200, 2.5 c.cm. Headache appeared on the second day and persisted for five days. Diplopia was complained of on the fifth day and persisted for two weeks. Right abducens affected. Oct. 21, 1944: Esophoria 4 P.D.; right vision 6/6; left vision 6/6; fundi normal.

Comment

Apart from the incomplete unilateral abducens paralysis no defects were noticed, except that Case 1 complained of "double hearing" for a time, and Case 3 had slight ptosis and anterior polar cataract, which were congenital in origin. Of the 10 cases reported 6 were female and 4 were male. The right abducens was affected in eight instances and the left in two. All the patients considered the headaches and double vision the most distressing part of their surgical experience, and some stated that the headache was almost intolerable. Ochaporski (1942) writes: "The aetiology of 282 cases of paralysis of the sixth nerve was . . . spinal puncture, 21. The frequency of sixth-nerve paralysis following spinal anaesthesia led Russian surgeons and gynaecologists to abandon this form of anaesthesia."

During the period under review spinal analgesia was administered to 2,021 patients. Ten of these developed paralysis of the sixth nerve. Though the number of cases is not large it indicates that abducens paralysis may be expected to occur once in every 202 cases after spinal analgesia. Premedication was given in all cases, and in a number of instances the lumbar injection was supplemented by the use of general anaesthetics—gas-and-oxygen, pentothal, and others.

Summary

Sixth-nerve paralysis and diplopia after spinal analgesia are discussed.

A theory is developed and a contributing factor presented to account for the diplopia and frequent early failure of the abducens in cerebral lesions, founded on the instability of the binocular vision function—phylogenetically a recently acquired attribute in man.

Ten instances are recorded of abducens paralysis following 2,021 cases receiving spinal analgesia.

The Ministry of Education has issued an administrative memorandum on the position of speech therapists employed by local education authorities in connexion with their provision for children suffering from stammering and other forms of speech defect. For some years the work of the speech therapist has been regarded as primarily educational, and the majority of those employed by local education authorities have in fact been recognized or approved as specialist teachers under the Code of Regulations for Public Elementary Schools. Recently, however, there have been changes in the courses of training for speech therapists and in the work on which they are employed. In England the training is now given in four training schools, each of which is maintained by, or conducted in close association with, a hospital and comprises instruction in anatomy and physiology; neurology; pathology of the ear, nose, and throat; phonetics and speech therapy. It does not include training in teaching, in handling classes of children, or in school practice. Correspondingly the work which the speech therapists have to do has been decreasingly educational and more curative. It is carried out, in part at least, under medical supervision, and the only persons whose employment as speech therapists is approved by the Minister of Education are those who have been admitted to the *Register of Medical Auxiliaries*. In these circumstances the Minister proposes that as from Nov. 1, 1945, speech therapists employed by local education authorities shall be treated as members of the staff of the school health service and shall not ordinarily be regarded as teachers.

TYPHOID FEVER COMPLICATED BY BENIGN TERTIAN MALARIA

BY

A. S. BOOKLESS, M.D.
Major, R.A.M.C.; Medical Specialist

AND

J. M. NAFTALIN, M.B., D.P.H.
Major, R.A.M.C.; Pathologist

(From a Military Hospital, M.E.F.)

The difficulties in making an early diagnosis of enteric fever are considerably increased if the patient is already suffering from other febrile diseases. We are here describing our observations on 34 patients with typhoid fever, because 10 of them also had benign tertian malaria. In two others the onset of malaria preceded that of typhoid fever by 17 days. Other conditions, such as sinusitis, recent T.A.B. vaccination, and suspected hepatic amoebiasis, caused confusion; while in two cases the question of kala-azar was raised.

The majority of our patients admitted to a Middle East hospital during the autumn of 1944 were involved in two small epidemics (see Table I). The first eight to arrive, all of whom suffered from a similar febrile illness, came from an Italian prisoner-of-war camp hospital. Benign tertian parasites had been found in the blood of two of them. All had received antimalaria treatment, but none had responded. The death of one of them from perforation of the small bowel finally revealed the true state of affairs. Investigations failed to show the source of this epidemic. Sixteen British patients from one mess in a malarious site were infected by a typhoid carrier—a native employed in the mess kitchen.

Table I.—*Distribution of Cases before Admission*

An Italian P.o.W. camp	14 (2 with concurrent B.T. malaria)
A static British unit	16 (8 " " " " ")
A British unit in transit ..	3 (No malaria)
Sudanese ghaffir	1 (" ")

Most of the recognized clinical manifestations of an enteric fever were present at some time, and they are classified in Table II. We propose to discuss only a few of them.

Table II.—*Chief Clinical Manifestations*

	Typhoid Fever (24 patients)	Typhoid with Concurrent B.T. Malaria	Total
Infections:			
Benign tertian malaria (concurrent only)	—	10	10
Miscellaneous:

Bronchopneumonia	2	0	2 (terminal)
Pleural effusion	1	0	1
Urinary:			
Albuminuria (temporary) ..	4	2	6
Typhoid pyelonephritis	1	0	1

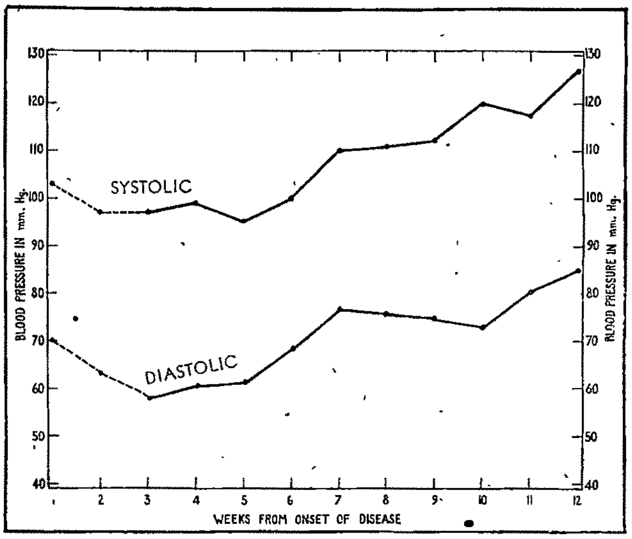
Clinical Manifestations

Fever.—Only on two occasions did the temperature charts suggest double infection—showing alternating hectic and remittent fever for the first four days. The other eight patients with both infections had an irregular remittent fever at the onset which became intermittent during a prolonged lysis (see Table III). Only one had a relapse (not malaria), whereas eight patients suffering from typhoid fever alone had relapses—which on three occasions exceeded the initial attack in length and severity.

Table III.—*Severity of Typhoid Fever in Relation to Concurrent B.T. Malaria*

	Severity					Fever	
	Mild	Moderate	Severe	Deaths	Total	Relapses of Fever	Average Duration Initial Fever (Days)
Typhoid fever only	12	6	3	3	24	8	22
Typhoid, with B.T. malaria concurrent	4	3	3	—	10	1 (Not malaria)	29
Total ..	16	9	6	3	34	9	24
No T.A.B. ..	—	—	—	1	1	1	—
T.A.B. vaccination incomplete	3	2	—	1	6	1	27

Circulatory System.—Relative bradycardia was present in 17 cases, only three of which had malaria. The pulse rates increased towards the end of prolonged fever and during relapses, and were unstable during convalescence. Twelve patients had a dicrotic radial pulse during the first weeks of illness. Blood pressures were always low during the first five weeks, returning to normal about the tenth week. The weekly average blood pressures of seven severe cases observed over a long period are shown in the accompanying Graph.



The weekly average blood pressure in 7 severe typhoid cases. There was no significant difference between the B.P. in typhoid alone (3 cases) and concurrent typhoid and B.T. malaria (4 cases). The averages were compiled from readings taken every third day.

Although apparently unrelated to fever, relapses, pulse rate, dicrotic pulsation, or concurrent B.T. malaria, blood-pressure readings proved useful as indices of the general condition and as guides during convalescence.

Respiratory System.—Nasopharyngitis and tonsillitis were common during the first three weeks. Two malarial patients were found to have frontal and maxillary sinusitis respectively. Typhoid fever—the third concurrent febrile disease—was recognized only when they failed to respond to treatment for the other two diseases. Subacute bronchitis occurred after the fourth week—sometimes as an exacerbation of chronic bronchitis. One patient developed a small pleural effusion associated with a relapse of fever.

Exanthem.—Only four patients had a recognizable enteric rash, but one or two doubtful maculae were seen on seven others.

Spleen.—Enlargement of the spleen was noticed on 15 occasions (44%). The incidence in doubly infected patients was 50%, and in patients with typhoid fever alone 42%. The sera of two non-malarial patients whose spleens were considerably enlarged reacted positively to Chopra's antimony test and to Napier's aldehyde test. No leishmania were found in smears from sternal bone-marrow (both cases) or the spleen (one case post mortem).

Liver.—The livers of nine patients were found to be slightly or moderately enlarged during the first five weeks of illness. Only one of these patients had both infections.

Fatal Cases.—Essential facts about the three patients who died are shown in Table IV. None of them were British. Not one of the doubly infected patients died, although they were febrile for a longer period than the average (see Table III). The warnings of Bhatnagar (1944) concerning the dangers of delayed diagnosis, lack of rest, and the administration of anti-pyretic drugs in typhoid fever are exemplified in the deaths of two Italian patients.

T.A.B. Vaccination.—One patient who died (Table III; Table IV, Case 3) received a full quota of T.A.B. vaccinations. A second was partially protected; the third had had no T.A.B. vaccine. Table III shows the relation between the severity of the attacks of typhoid and T.A.B. vaccination state. The data do not provide sufficient grounds for any conclusions. Four British patients were admitted within three days of T.A.B. vaccination apparently suffering from severe reactions. *B. typhosus* was cultured from the blood taken on the second, third, third, and eleventh days respectively after administration of the vaccine. Apparently these were the only four patients who received the new alcoholized vaccine.

TABLE IV.—*Deaths*

Case	Age	T.A.B. Protection	Day of Death After Onset	Outline of Course of Disease	Necropsy
1	34	Incomplete (0·5 c.cm.) 1 month before admission	14	Gradual onset with diarrhoea. Treated for this and for malaria in camp. 11th day: small haemorrhage. 12th day: meteorism, abdominal pain and rigidity	Many typhoid ulcers in ileum. One ulcer had perforated—purulent peritonitis
2	28	No protection	23	Temperature normal by 6th day; relapse fever, 8th day; 2nd blood culture positive 12th day; intestinal haemorrhage 21st day. Napier's and Chopra's tests positive	Spleen showed typical typhoid changes. No Leishman-Donovan bodies seen
3	34	Full quota T.A.B.	45	Persistent high fever. 3rd week: meteorism. 20th day: haemorrhage followed by remission and improvement. Finally died in typhoid stupor	Many typhoid ulcers in ileum. Broncho-pneumonia

Diagnosis

In 28 out of 34 cases *B. typhosus* was cultured from the blood —taken as early as the second or as late as the 24th day of the initial fever. Here we should mention that it is not always possible to decide with accuracy the date of onset of typhoid fever, especially in cases with mixed infection. Apparently, recent or simultaneous administration of quinine, mepacrine, or pamaquin does not reduce the chances of obtaining a positive culture. The first blood culture was positive in 26 out of 28 cases. In the remaining two *B. typhosus* was cultured from the blood at the second and the third attempt respectively. Positive cultures of urine (1) and faeces (1) established the diagnosis in two other cases, whereas another was diagnosed post mortem the day after admission.

A diagnosis of typhoid fever was eventually made on three occasions in spite of repeatedly negative cultures of blood, urine, and faeces. These three patients, of whom two also had malaria, were the first arrivals from a British unit.

We attached little importance to the leucocyte counts, as the results were usually compatible with the diagnosis of either of the two prevalent diseases. "O" and "Vi" agglutination tests were not carried out systematically. No conclusions can be drawn from our incomplete results, which are therefore omitted.

Discussion

Medical officers still too often fail to consider the possibility of a double infection during the first week of illness. We have found that patients with uncomplicated B.T. malaria always improved on quinine. Tests of the urine of some of our patients with Tanret's reagent showed that quinine was being absorbed.

Our initial examination seldom revealed any signs suggestive of an enteric infection. Temperature charts gave us little help. The pulse rates of doubly infected patients were as a rule proportionally accelerated.

A typhoid rash was observed on only four occasions during the second week of disease. The finding of splenic enlargement was no help to diagnosis. So far we have not observed the blood-pressure changes during the last two weeks often enough to enable us to judge whether they are constant or specific.

Evidently the only two *early* distinctive signs of an enteric fever—progressive stadium incrementi and relative bradycardia—may both be absent, especially in patients simultaneously afflicted by some other febrile disease, such as B.T. malaria.

The value of taking blood for culture is diminished if it is postponed until the full enteric syndrome has developed.

Summary and Conclusions

We have recorded observations on 34 patients suffering from typhoid fever, three of whom died.

The early clinical diagnosis was hindered on 12 occasions by the simultaneous presence of or immediate recovery from B.T. malaria. None of those suffering from malaria died.

Blood pressures were low during the first five weeks and did not reach normal levels until the tenth week.

B. typhosus was cultured from the blood in 28 out of 34 patients.

Blood cultures should be carried out early and repeatedly while the cause of fever remains unknown.

Blood cultures should always be carried out when there is a relapse of fever, whatever the initial condition.

We wish to express our gratitude to Col. A. C. MacDonald, *M.C., T.D.*, our late commanding officer, for permission to publish these cases; and to Lieut.-Col. J. Gibson-Graham, officer in charge of the Medical Division, for his advice and help.

Medical Memoranda

Neurological Complications in Cerebrospinal Meningitis treated with Penicillin

The following case, in which neurological complications arose after treatment with penicillin, may be thought of interest.

CASE HISTORY

On June 30 the patient, a boy aged 12, was "off colour"; he had no definite complaints and was not confined to bed. Next day he complained of headache and stiffness of the neck; his face was flushed. His parents thought it was a chill or influenza, and, it being Sunday, did not call for medical aid. The family doctor was called early in the morning of July 2 and found the boy unconscious but extremely restless, with flushed face, increased pulse and temperature, and neck rigidity. The patient was removed to hospital in an unconscious state. Lumbar puncture was performed; the fluid was very turbid and under pressure. The laboratory report was as follows: Cells, 45,000 per c.mm.; protein, 350 mg./100 c.cm.; chloride, 630 mg./100 c.cm. Gram film: polymorphs +++; Gram-negative intracellular diplococci. Meningococci were isolated on culture.

The patient was put on sulphapyridine treatment on July 2 and 3 (8 g. in 24 hours), but he continued unconscious and was extremely restless. The temperature remained in the region of 103° F. and the neck rigidity was more pronounced, almost amounting to opisthotonos. Strabismus with unequal pupils and a left facial paresis developed; knee-jerks were exaggerated and the plantar reflexes were flexor. There was incontinence of urine and faeces. Apparently he was not responding to sulphapyridine treatment, so penicillin was substituted on the evening of July 3. The first injection of 18,000 units was given intrathecally; the cerebrospinal fluid had now become very purulent and thick, and was withdrawn with difficulty. Subsequent injections of 18,000 units were given intramuscularly every 3 hours. The patient was still unconscious, and became extremely restless after the intrathecal injections.

July 4.—Lumbar puncture; fluid less purulent but still under pressure. Laboratory report: Cells, 3,000 per c.mm. Gram film: cells, polymorphs; no organisms seen. Culture, sterile. Penicillin 18,000 units was given 3-hourly, once intrathecally. The treatment was continued 3-hourly for 5 days, three injections being given intrathecally, the remainder intramuscularly.

July 5.—The patient regained consciousness and became quieter. The neck rigidity persisted, but the temperature had dropped to 99.4° F.

July 6.—Temperature normal; patient able to talk rationally and take nourishment. The strabismus and inequality of pupils disappeared and the facial paresis cleared up.

July 8.—The patient received the last injection of penicillin at 4 p.m., and by 8 p.m. he developed a marked oedema of the anterior aspect of the neck, extending from the root of the neck to the thyroid cartilage. The temperature had risen to 99.2° F. The neck rigidity was still present, but was much less marked. Sulphadiazine 1 g. was given 4-hourly, and by the next morning the oedema had subsided.

July 9–15.—The patient steadily improved; the neck rigidity became gradually less severe and the temperature was normal, but on July 10 a flaccid paresis of the left arm developed, affecting the trapezius, deltoid, biceps and triceps, and forearm muscles, with a wrist-drop. The muscles were painful to touch or on movement. The arm was abducted, placed on a pillow, and an electric pad applied. From July 10 to 15 the condition improved and function returned to the trapezius, forearm muscles, and extensors of the wrist; the deltoid and biceps remained paralysed. During the evening of the 15th the patient suddenly cried out, and it was discovered that he had lost the power of speech. There was a right facial paresis; the pupils reacted to light and accommodation; the tongue deviated to the right side; and a spastic paresis had developed in the right leg, with exaggerated knee-jerks, sustained ankle clonus, and a doubtful extensor plantar response. The temperature rose to 99.8° F.; pulse 104. Sulphadiazine 1 g. 4-hourly was given, but within 4 hours the temperature had dropped to normal, the power of speech was restored, and the right facial paresis and the spastic paresis of the right leg had disappeared. The flaccid paresis of the left upper arm remained. The exaggerated knee-jerks, extensor plantar, and ankle clonus had gone.

July 16–23.—General progress was maintained; temperature remained normal, full movement of the neck was obtained, and the only remaining paresis was in the deltoid and biceps of the right arm. He was discharged home on July 23.

The patient was seen on July 31 by the orthopaedic surgeon, who recommended massage and electrical treatment, and suggested that the prognosis for full recovery was very good.

After three months' massage and electrical treatment the deltoid and biceps muscles fully recovered. He has been discharged from the orthopaedic hospital and is completely well, and there is now no evidence of any neurological lesion.

Barrow-in-Furness.

Myxoedema induced by Thiouracil

The reported harmful effects of thiouracil have included various transient symptoms, granulocytopenia, and purpura and other rashes, but examples of gross depression of thyroid function are rare. In the following case clinically obvious myxoedema appeared after a total dosage of 39.8 grammes in 4 months.

CASE REPORT

About nine months after the birth of her first baby a woman aged 24 complained of being easily tired. Her hands were moist and tremulous and her eyes staring. A diffuse enlargement of the thyroid gland was present (neck circumference, 13¾ in.). Her weight, usually over 9 st., had fallen to 8 st. 2 lb. A clinical diagnosis of primary hyperthyroidism was made and she was given thiouracil 0.6 g. daily for one week and then 0.4 g. daily for two weeks. White cells at onset of treatment numbered 7,200 per c.mm. She left hospital after three weeks and continued on 0.2 g. daily for one month, feeling very much better. White cells, 10,800. She did not attend hospital during the next two months and obtained her treatment elsewhere. Dosage was 0.4 g. daily.

When next seen it was at once obvious that a striking change had occurred. Her face was puffy and she looked coarse and dull. Her voice was deep, and her hair was falling out. Her fingers were swollen so that her ring could not be removed. She complained of aching pains in the limbs and felt the cold greatly. Her weight had increased fairly suddenly by 1 st. and the neck circumference was 15 in. Menses remained unchanged at 4/28. The heart rate was around 50; B.M.R., − 20; plasma cholesterol, 330 mg. per 100 c.cm.; white cells, 8,500.

Cessation of thiouracil and administration of thyroideum siccum 1/2 grain twice a day brought her back to normal appearance and a feeling of well-being in about three weeks.

Chase Farm Hospital, Enfield.

C. ALLAN BIRCH, M.D.

Further regulations permitting certain persons not covered by the regulations made under the Nurses Act, 1943, to use a title including the word "nurse" have been made by the Minister of Health and the Secretary of State for Scotland. Persons who are 18 or over, and are gaining experience under trained nurses in a hospital or institution with a view to admission to the roll of assistant nurses as "intermediate" assistant nurses, may call themselves "probationer assistant nurses."

Reviews

METHODS OF APPROACH IN LIMB SURGERY

Extensile Exposure Applied to Limb Surgery. By Arnold K. Henry, M.D., M.Ch., F.R.C.S.I. (Pp. 180; illustrated. 30s. plus 7d. postage.) Edinburgh: E. and S. Livingstone. 1945.

Mr. Arnold K. Henry's publications on novel and ingenious methods of approach in surgery are well known, and owing to the sound anatomical principles upon which they are based they have been much utilized in the practice of the art; further, the originator's claims for them have not proved false. He has now collected and elaborated such of this material as applied to limb surgery in a book entitled *Extensile Exposure Applied to Limb Surgery,* a somewhat clumsy title, though it is difficult to see how the author could otherwise have indicated its scope. What "extensile exposure" means he reveals in the preface: "Exposure that will vie effectively with the 'great arsenal of chance' must be a match for every shift, and therefore have a range *extensile,* like the tongue of a chameleon to reach where it requires." This, then, indicates the nature of the contents of a book for which we have nothing but praise. Many of the exposures described are quite novel, and the anatomical and surgical reasons for their choice are made abundantly clear and further emphasized by a large number of excellent drawings. The reproduction of these upon art paper has allowed them to keep all their original quality, and puts the book into the high grade of medical publications which we come to associate with the name of E. and S. Livingstone, Ltd.

In the effort to make his points easy to understand and remember the author, professing his inability to share the artist's gift of recalling "the un-Euclidean visage of anatomy," has not disdained to use whatever crutch or simile or dodge has proved its worth, such as "satellites, loopholes, half sleeves, shoulder straps, cloaks, seams, leashes, bucket handles, lids, sandwiches, Vs, and manual mnemonics."

So far we agree, but it perhaps seems a little incongruous to find mixed up with all this copious quotations from the classics and philosophers, for the style of writing is what may be somewhat loosely described as "literary." One cannot fail to be impressed by the author's erudition, or by the aptness of his quotations; we certainly would not wish to criticize the style, but we may be allowed to comment. We recognize that there are differing schools of thought as to whether a scientific writing should aspire to literary merit, and come down heavily in favour of it, and Mr. Henry; but even so we cannot help wondering if the following footnote (there are others like it) does not savour rather too strongly of pedantry. "Recognise, recognize; mobilise, mobilize, etc. The *Oxford English Dictionary* is strong for 'z.' But Pater, who was 'Oxford,' allows the 's'—like Quiller-Couch of Oxford *and* Cambridge. I shall abide by Kent's uncompromising verdict (*King Lear,* Act II, Sc. 2)." If the surgeon faced with the necessity for extensilely exposing the femur is really concerned about the "whoreson zed! thou unnecessary letter," any zany can remind him with zest (the operation we hope being successfully completed meanwhile) that descriptive medicine would be seriously handicapped without its zygote, zymotic, ziphi, zygoma, to say nothing of the difficulties in his zoological studies before the student reaches his zenith. Even Mr. Henry's compositor could not entirely discard his font of "zeds," nor his most skilful artist, Miss Zita Stead, her name. But perhaps we are wrong; anyway this book is a notable contribution to surgical literature.

PATHOLOGY

Pathology. An Introduction to Medicine and Surgery. By J. Henry Dible, M.B., F.R.C.P., and Thomas B. Davie, M.D., F.R.C.P. Second edition. (Pp. 946; illustrated, including 8 plates in colour. 45s.) London: J. and A. Churchill. 1945.

The publication of a second edition of Dible and Davie so soon after the first is ample evidence of its popularity with medical undergraduates in this country. It provides a straightforward and clearly written account of the views of the majority of British pathologists. It is not overweighted with histological and cytological minutiae which have neither interest nor educational value for the clinical student. On the other hand, the correlation between changes in structure and clinical signs and symptoms is heavily stressed.

The chapters dealing with the acute infections are particularly instructive. The senior author's long experience as a microbiologist has obviously enabled him to strike a true balance between the bacteriological and immunological problems presented by these diseases and the structural changes they cause in the tissues. This broad treatment of infection in a textbook of pathology not only stimulates the student's interest but is of very considerable educational value.

The illustrations are well chosen, the diagrams are instructive, and the book is neither heavy nor cumbersome. It has obviously established itself as a reliable and well-planned standard textbook.

TWO BOOKLETS ON NUTRITION

Nutrition. By W. R. Aykroyd, M.D., Sc.D. Oxford Pamphlets on Indian Affairs, No. 21. (Pp. 32. 9d.) London: Oxford University Press.

Manual of Nutrition. By Rose Simmonds, S.R.N. (Pp. 90. 1s.) London: Cassell and Co. 1945.

Nutrition, by Dr. W. R. Aykroyd, is No. 21 of the Oxford Pamphlets on Indian Affairs. In it the author gives details of India's food production and the composition and defects of typical Indian diets. He points out that the diet of the mass of the population is grossly deficient in quality and usually in quantity, and that much of the ill-health and disease in the country can be attributed to malnutrition. The economic aspects of nutrition and the population problem are briefly discussed, and finally methods for improving the nutrition of the country are suggested. Malnutrition in India cannot be prevented by teaching the masses what to eat when it is not available. Developments and changes in agricultural production are needed to make the food supply satisfactory, and economic reform must ensure that all are able to buy an adequate diet. It is a pity that this booklet is printed on such poor-quality paper.

The little book by Miss Rose Simmonds, which was written at the request of the British Red Cross Society for the use of its members, may be described as nutrition in a nutshell. The treatment is essentially practical. After describing the different food elements, the author gives the composition of the common foods and their place in the diet. There are also chapters on suitable diets for infants, school-children, adolescents, sedentary and active workers, and expectant and nursing mothers. At the end of the book is a comprehensive table giving the composition and vitamin content of common foods. Useful information is also given on the best way to cook foods so that the vitamins are conserved as much as possible. The style is brief and to the point, and the book is free from technical jargon, so that it can be understood by the layman without previous knowledge of the subject. A useful handbook for the mother of a family.

A VIEW OF SEX

A Psychologist Looks at Sex. By Howard L. Philp, Ph.D. (Pp. 110. 8s. 6d.) London: Hutchinson's Scientific and Technical Publications.

In dealing with sex it is very difficult not to be either ribald or smug, and in published works on the subject there is practically always a tendency to smugness. The present book is no exception to this rule. The author starts with the premiss, to which most people will adhere, that the only satisfactory situation in which sex can be successfully practised and enjoyed is in monogamous marriage with the foundation of a family as its chief end. He then proceeds to bring evidence to support this premiss, but the reader cannot help feeling, if he is really detached, that the evidence is highly selective and that the whole tone of the argument is didactic rather than strictly scientific.

This is one of the few books which does not cloak its didactic nature by a pseudo-scientific discussion, with diagrams, of the anatomy and physiology of the sex organs, and this omission is certainly to be commended. The chapter on the influence of the personal attractions and repulsions of early childhood on the subsequent capacity of the individual for love is admirable, but the author's criticism of the work of Freud lacks depth of understanding.

As an exposition of the ideals to be aimed at in the love life of the normal individual this volume is excellent; but it is doubtful if there is really a sufficiently deep and sympathetic understanding of the difficulties which beset so many people in modern society, where economic and social factors make early and continuously happy marriage so very difficult.

Notes on Books

To assist doctors, nurses, and other persons looking after the health of displaced persons, U.N.R.R.A. has produced a comprehensive *Medical Manual.* The first part gives general information about U.N.R.R.A. and its health organization; the second deals with the health problems of displaced persons; and the third contains eight chapters on such special problems as nutrition, maternity and child welfare services, communicable diseases, immunization, and disinfestation. The *Manual* is available in the library of the B.M.A.

Accompanying the annual report of the British Council for 1944–5 comes an interesting booklet outlining the work of its Science Department, whose activities are directed by Mr. J. G. Crowther under the general advice of a committee of distinguished men, with Sir Henry Dale as its chairman. The Science Department has panels for medicine, engineering, and agriculture. A printed scheme of the organization shows that medicine has an impressive place in it, under the directorship of Dr. N. Howard Jones. The most familiar product of the department's activities is the *British Medical Bulletin,* the function of which is to record for the benefit of foreign readers surveys of current British medical literature.

An interesting picture of efforts to combat microbic infection in the U.S.S.R. during the war is given in *Microbiology and Epidemiology,* by various authors, translated from the Russian by Dr. H. P. Fox (London: Medical Publications Ltd.; 15s.). It is a volume in a series recounting the "Achievement of Soviet Medicine in the Patriotic War" and was published in the U.S.S.R. in 1943: its rather propagandist flavour was therefore designed originally for home consumption. The principal subjects dealt with are immunization against typhus, cholera, dysentery, and tetanus, the destruction of disease vectors, the use of bacteriophage in preventing or treating cholera and gas gangrene, and among chemotherapeutic agents "phytoncides," gramicidin, and penicillin. Like many papers in the *American Review of Soviet Medicine,* which has been a valuable source of information about medical progress in the U.S.S.R., the accounts given in these chapters are only of a general nature, with neither the technical details nor the statistical data on which to base any serious judgment. The prevailing note of optimism consequently awakes a rather subdued echo in the reader's mind, particularly in connexion with some of the newer and more peculiar forms of treatment advocated.

The Pioneer Health Centre has issued from 8K, Hyde Park Mansions, Marylebone Road, N.W.1, a pamphlet (price 1s.) bearing the title *Observations on the Population Question.* This is a memorandum presented to the Royal Commission on Population by Dr. INNES H. PEARSE, and the facts given and the opinions expressed have been drawn from studies of some 1,500 families that have passed through the Health Centre at Peckham. Part I leads to the conclusion: "No bigger mistake could, in our opinion, be made than to conclude that contraceptives are the predominating *cause* of the fall in the birth rate. Contraception is a method; the fall in the birth rate is the consequence of some deeper underlying factor." Then follows a discussion of methods for family limitation and conditions operating to limit the size of the family, and from this the general conclusion is drawn that the cause of a falling birth rate is a matter for direct experimental research by trained scientists searching for the natural social conditions which will promote parenthood.

The *Yorkshire Post* has described a plan put forward by the Medical Faculty of the General Infirmary at Leeds to provide, as a 1939–45 War Memorial, a model "health village," within easy access of the city, for general and surgical cases in need of long-term treatment. The proposal is to expand the original long-stay hospital idea into a country village scheme, with hostels for after-care, houses and flats for doctors and nurses and other staff, administrative offices, shops, schools, workshops, and market gardens, and other facilities for rehabilitation and vocational training; also a village hall, cinema, and theatre for entertainment, as well as a single general hospital for treatment. The Medical Faculty recommends provision for about 850 patients, adults and children—500 in the hospital and about 350 outside, which would mean a village population of between 2,000 and 3,000. The Yorkshire Regional Hospitals Council set up a subcommittee to investigate and discuss the problem, and the "health village" outlined is its suggestion for meeting the need in a country site reasonably near Leeds.

SATURDAY DECEMBER 8 1945

CONTROL OF MALARIA IN THE TROPICS

The part that research is likely to play in the future in the development of our Colonies is very clearly brought out in the recently issued official pamphlet entitled *Colonial Research, 1944-45.* It includes the second annual report of the Colonial Research Committee, which, among other things, records the findings of the Colonial Medical Research Committee. This committee, constituted jointly by the Secretary of State and the Medical Research Council, with Sir Edward Mellanby as chairman, deals in its report with two points of outstanding importance relating to malaria. These are the extent to which the new insecticide D.D.T., of which field trials have recently been made under the direction of the committee in British Guiana, is likely to influence malaria control, and the question how far the development of new synthetic drugs should affect the policy of cinchona cultivation in the Colonies. It is pointed out that, while D.D.T. will undoubtedly provide a very powerful weapon against malaria, it is not likely that the promise shown by it or any other like substance will as yet justify relaxation of orthodox and tested antimalarial measures, though a careful review of these should be made. This conservative estimate of the part likely to be played by D.D.T. is apposite at the present time, when lack of knowledge of the intricate and varied nature of malaria control may give rise to exaggerated ideas of what can be immediately accomplished. What changes this new and remarkable insecticide may bring about can in fact be left to those who have already done so much to develop methods of control.

The second of the points referred to brings to the fore important matters of policy, and a difficult decision has to be made. What should be done about cinchona cultivation? The reason for growing it at all at present is that in spite of the proved efficacy of atebrin, and now of the new compound paludrine, quinine may still have a place in the treatment of malaria and still be the safest drug for general employment without medical supervision. That atebrin could replace quinine even for the second purpose is not so debatable as was at one time thought, for experience has tended to lessen the likelihood of untoward effects from it. But it is still possible that Governments and sanitary authorities may wish to be on the safe side and so prefer quinine for general distribution. There is even more at issue than this, for a quite different policy is required depending upon whether the cultivation of high-grade cinchona varieties most adapted for the manufacture of the pure alkaloid quinine is to be encouraged, or that of quite other varieties if the view is accepted that what is mainly required is not pure quinine but some form of cheap product containing the total alkaloids of cinchona. In the latter case it is usual to elect for some minimal percentage of quinine itself, and this may not be easy to conform to if the low-grade quinine-yielding cinchonas are too exclusively cultivated. Again, how far is the view correct that what is wanted is above all a cheap product? Preparations of the total alkaloids can scarcely but be looked upon as an inferior article even by the poor, and it might be wiser for this and other reasons to elect for the pure drug with the cheapest possible production. It would seem, therefore, in view of so much uncertainty, that the committee has been wise to recommend a scheme of research and development in relation to the growing of cinchona in the Colonial Empire based on East Africa. In this way it is hoped to work out what the proper production policy should be.

The right policy for malaria control is also discussed in the report of the fifteenth annual meeting of the Ross Institute Industrial Advisory Committee. Dr. George Macdonald, the Director of the Institute, refers in this to the remarkable scheme carried out lately by the Yellow Fever Control Service for eradicating *Anopheles gambiae* in Brazil. It was started in 1939 and was based on the principles used in the control of yellow fever. By September, 1940, nineteen months later, this dangerous mosquito, which had invaded the New World from Africa, had been wiped out of Brazil—well worth the two million dollars spent on the project. A similar campaign has now been started in Egypt over 300 miles or more of the Nile Valley, and Dr. Macdonald foresees similar operations in Mauritius, the Seychelles, and other places where conditions are favourable. He appreciates the many valuable applications of D.D.T., but points out that it will not be a panacea—the greatest difficulty in mosquito control is the maintenance of adequate supervision.

Still another important contribution bearing upon research into malaria and its control, this time in India, appears in the section recording the work of the Malaria Institute of India in the report for 1944 of the Scientific Advisory Board, Indian Research Fund Association. The headquarters of the Malaria Institute are at Delhi, but its activities extend throughout India, and it advises upon, initiates, and carries out malaria survey, research, and control, and at the same time acts as a training centre and teaching school. It publishes its own journal—one of the few wholly concerned with malaria—has its own complete reference library and collections, issues technical bulletins on different aspects of malaria, and generally acts as a permanent centre for malaria work in India. During the war it has played an active part in providing and training officers and personnel for the large number of malaria units engaged in control work with the military authorities in India, Burma, and other countries in the Middle East. As the report notes, the carrying-on of its normal peacetime functions has been much curtailed, and research has been confined largely to that on insecticides, repellants, protection by impregnated clothing and netting, and other problems of immediate military importance. Among more normal peacetime items, however, is a reference to a critical statistical study of the present method of forecasting the occurrence of epidemics. These violent manifestations of malaria with their heavy mortality are a feature of

North-West India, and to be able to foretell their onset, and so enable early arrangements to be made for distribution of quinine and various forms of public assistance, is an important aspect of malaria control. The practical bearing of such research is a good example of the variety of ways in which the control of malaria must be tackled. It also serves to illustrate the need for specially trained workers in various branches of research. It will not be inappropriate in this connexion to turn back to the recommendations made by the Colonial Medical Research Committee; it points out that in regard to medical research in general the way is now clear for a rapid and systematic attack on the major medical problems of the Colonies. But it feels bound to point out that research cannot be prosecuted effectively in this field without a regular flow of skilled scientists, and expresses the hope that, to meet this need, energetic steps will be taken in co-operation with British universities. These remarks of the committee refer especially to the shortage of entomologists; but malaria control is far from being merely an entomological problem, and there is great need also for the trained medical observer —a fact which is sometimes apt to be overlooked.

EPIDEMIC RISKS IN EUROPE

Of the international quarantine diseases, yellow fever has been absent from Europe for very many years and cholera since 1925. There remain smallpox, plague, and typhus. The head of the Epidemics Control Branch of U.N.R.R.A., Dr. George Stuart, who was formerly with the Colonial Medical Service in Palestine, at a recent Press conference drew an epidemiological map of Europe, pointing out the main epidemic risks. Smallpox at present is to be found only in Italy; in Dr. Stuart's words, it has been "largely vaccinated out of Europe." Plague is to be found only in Malta, although so long as ports in the Suez Canal, West Africa, and Palestine remain plague-infected there is always a threat to the European coast of the Mediterranean. Typhus has been practically eliminated from the entire area lying west of a line drawn along the Elbe to the Adriatic. The black spots of residual infection east of the line are Slovakia, east and south, Hungary, in the north, Bosnia, Carpathian Russia, Poland, Rumania, Bessarabia, and Bukovina. Other countries affected to some extent are Bulgaria and Greece.

Of other epidemic diseases normally endemic in all countries Dr. Stuart mentioned diphtheria, the incidence of which is still high in France and Holland, and highest in Germany, particularly in Berlin. In Germany not only is the incidence abnormally high but there is an increased proportion of severe infections, together with a shift of the age groups affected from those under 15 to those over 15. Last year 30% of the deaths from diphtheria in Rostock in Germany were of persons over the age of 15. In a recent article in this *Journal*[1] Dr. Stuart, analysing the available figures, concluded that since 1941 the incidence of diphtheria in Northern and Central Europe has increased to an extent unparalleled since control of the disease became possible: it has become "the leading epidemic war disease on the European continent, both in morbidity and in mortality." The experience of England stands out in strong contrast to that of France, Germany, Belgium, the Netherlands, and Norway; in 1944 the diphtheria morbidity and mortality in England and Wales were the lowest ever recorded.

Scarlet fever is not now obtrusive; there is no change in type or gravity of the disease. Typhoid fever has greatly increased in the western countries of Europe and in Finland. There is a typhoid epidemic in Germany, where there was thirty times the normal incidence in September, and in Poland, where 46,800 cases were notified in the first nine months of the present year—a notification rate of about 1.3 to the 1,000 of population. The cause is the destruction of the water supplies and sewage disposal systems, together with inadequate nutrition in overcrowded and bombed areas. Dysentery is more prevalent than usual; this must be said of Great Britain as well as of Norway, Germany, and Austria. In Berlin and Vienna the case mortality is said to be 20%. Poliomyelitis was recently prevalent in Belgium and Bohemia, but there has been no extension to neighbouring countries; the incidence of cerebrospinal meningitis continues to decline. The last wave of influenza was in the winter of 1943–4: there has been no pandemic since the one which occurred at the end of the last war. Of endemic diseases the tuberculosis incidence has much increased in many Continental countries. It is especially high in Greece, Yugoslavia, and Italy. In Italy it has been found that from 2 to 4% of cases examined by mass miniature radiography need further investigation, as compared with something like 3 or 4 out of every 1,000 in England. Syphilis has shown a large increase in most countries—in Germany a twenty-fold increase. It is declared that control of venereal diseases has been set back nearly twenty years as a result of the war. Another endemic disease, malaria, is the leading cause of illness in a large part of the Mediterranean basin, and is of epidemic proportions in Greece.

Dr. Stuart concluded his survey by making three points. The situation in Europe to-day is not nearly so disastrous as it was at a comparable period after the war of 1914–18. No communicable disease at present has an incidence which constitutes a menace to international health. But the "hump" has not yet been passed, and it is impossible to forecast whether one or other communicable disease may not yet assume epidemic form during these winter months. Meanwhile U.N.R.R.A. is garrisoning devastated Europe with medical supplies. Up to the end of September this organization had shipped over 1,000 tons of medical and sanitary equipment and material, of a value of £4,387,000, to Albania, Czechoslovakia, Greece, Italy, Poland, and Yugoslavia, and to the U.N.R.R.A. camps. To combat epidemics in particular it included 100,000 doses of antiplague vaccine to Italy, 1,000 doses of antiplague serum, and 750 doses of antiplague vaccine flown to Belgrade in view of a threatened epidemic there, 400,000 sulphaguanidine tablets flown to Athens for use in a serious outbreak of dysentery, and 4,000 vials of an antimony compound to be employed against kala-azar in Yugoslavia. Under the new international sanitary conventions signed early in 1944 U.N.R.R.A. has temporarily assumed responsibility for exchange of epidemiological information, and for Europe this is centred in Dr. Stuart's branch of the Health Division in London. By arrangement with the International Health Office in Paris, the League of Nations, the various Governments, and the U.N.R.R.A. missions (staffs of doctors, nurses, and sanitary engineers in five countries, and medical liaison officers in four others) a constant stream of information is now coming in for analysis and being sent out again to Governments.

A LITTLE OF WHAT YOU FANCY

Some animals eat a limited range of foodstuffs; and it may well be supposed that they have an inherent preference for those specially suited to their constitutions. But rats are omnivorous, and experiments such as those of Gaunt, Irving, and Thomson[1] have shown that they may be induced to eat a diet so inadequate that a colony may come near to dying out in a few generations. Are rats that have a choice of food protected by an instinctive appreciation of nutritive values?

L. J. Harris and colleagues[2] at the Cambridge Nutrition Laboratory made a series of carefully controlled experiments on the relation of choice of food by rats to their requirements. Normal rats, given a choice between three jars of food, one of which supplied aneurin, ate about equal amounts of all three. But after a short time rats that had been depleted of vitamin B_1 ate the aneurin-containing food almost exclusively. However, rats depleted of vitamin A or D did not choose the food that would supply the vitamin they needed. Harris concluded that the rats were guided in their choice of food by the benefit felt shortly after eating aneurin, and that they had no instinct to lead them to eat foods the benefit of which would be perceptible only after some time. This conclusion is supported by Kon's experiment,[3] in which rats offered casein and sugar (or starch), separately, ate so little protein that they did not grow; whereas rats given casein and sugar mixed grew well. This interpretation of the choice made by rats puts it on a level with the refusal by human beings of foods "that do not agree with me." It is one stage beyond the consumption of stimulants for the sake of the immediate effects, despite a "hangover" within a period short enough for the *propter hoc* to be appreciated. Richter's experiments on the choice of food by rats with endocrine deficiencies admit of the same interpretation. After adrenalectomy rats consumed about fifteen times as much sodium chloride as before[4]; after parathyroidectomy rats consumed large amounts of calcium salts and avoided sodium phosphate.[5] After incomplete pancreatectomy[6] rats promptly increased their consumption of carbohydrate, protein, and vitamins of the B group. But after a variable period the consumption of fat was nearly trebled and that of carbohydrate reduced to under one-half, while that of protein was increased by about a half; the consumption of the B-group vitamins, with the exception of choline and nicotinic acid, was then about twice the pre-operative level. After operation the rats were lethargic, but when they began to eat large amounts of fat they became active again, and they no longer passed large quantities of urine or drank corresponding amounts of water. Owing to possible errors of technique, Richter and his colleagues did not consider that the change of appetite for B-group vitamins was more than suggestive. But this increased appetite is in agreement with experiments in which depancreatized dogs required more insulin when these vitamins were withdrawn from their diet.[7]

A comparable adjustment of diet to requirements was noted by Higgins.[8] Young rats being treated with promin (promanide), used in the experimental therapy of tuberculosis, developed a craving for aneurin, riboflavin, and pyridoxine. An increased intake of these vitamins was found to counteract the toxic effects of promin. It may be supposed that in all these experiments the rats learnt from experience. The benefits of a high-fat diet after pancreatectomy are less obvious than those of high-salt and high-calcium diets after adrenalectomy and parathyroidectomy, and the rats, in consequence, took longer to adapt their diets. There remain, however, the experiments quoted by Richter[9] in which rats given a choice of nearly pure foods grew as well on their own choice of food as on McCollum's diet, although they ate 15 to 40% less. This recalls the experiments of Davis,[10] showing that babies, judged by their health and development, made a highly satisfactory choice from a wide range of foodstuffs; one baby with rickets chose cod-liver oil until the rickets was healed.

Whether based on instinct or experience, the selections made by the rats were sound. Patients with Addison's disease crave for sodium chloride—like adrenalectomized rats. In human nutrition practice has been so far ahead of theory, until recent times, that we may wonder whether we should not pay greater attention to personal choice of food. The almost universal desire for meat may be evidence that meat has some nutritive value that we do not as yet appreciate. But in human choice the mouth is so much more important than the metabolism; human beings are so influenced by habits, prejudice, and wrong theories that these preferences must be viewed with suspicion. The Oriental's preference for polished rice—and beriberi—is a case in point. Even if preferences are sound they can but point to a possible goal. For the present most of us must eat what we can get, not what we would like.

AFTER-CARE OF HEAD INJURY CASES

The Nuffield Provincial Hospitals Trust, the Ministry of Pensions, and the Radcliffe Infirmary, Oxford, have had under consideration for 18 months the devising of a scheme for the after-treatment of head injury cases. The interest of the Nuffield Trust and the Radcliffe Infirmary in this question derives from the work done at the Military Hospital for Head Injuries at St. Hugh's, Oxford. The interest of the Ministry of Pensions flows from its responsibility for the treatment of disability arising from the war, and includes cases of head injury treated at special centres of the Emergency Hospital Scheme and in military hospitals. As a result of modern neurosurgery and chemotherapy, men with brain wounds have survived who formerly would have died. Many have regained much of their lost brain function; speech, sight, and mental faculties have returned, paralysed limbs have moved again. But recovery is often incomplete, and sometimes the permanent damage is severe. Inability to cope with the conditions of civilian life, coupled with the fear of being a drag on their families, causes such men anxiety, disappointment, and frustration. If they are to make their contribution to the community within the limitations imposed upon them their physical, mental, and vocational capacities for work must be assessed while they are in hospital. Later they must have simple training in various forms of work, more advanced and more satisfying than occupational therapy alone can afford. The gravely disabled must be given a permanent centre in and around which they can live with their families under the protection they need.

The following steps are now being taken to cope with this problem. In addition to the routine treatment provided by the Ministry of Pensions, there is need for research into the best methods of rehabilitation, and into other problems of head injuries. To carry out this research the Radcliffe Infirmary has, with the aid of £20,000 from the Nuffield Trust, appointed a neurologist, Dr. W. Ritchie Russell, who will work in close touch with the departments of Oxford University which are already studying lesions of the nervous system. One of his primary duties is to give special assistance and advice to the Ministry, so that the latest methods of treatment may be made available for pensioners.

TUBERCULOSIS IN WALES

Already the chief medical officer of the Welsh National Memorial Association is contemplating a resumed decline in the death rate from tuberculosis. During 1944 Wales was probably the only country in Europe able to report a substantial fall between the years 1938 and 1944, from 812 deaths per million to 715. A large part of this tactical success in the campaign against tuberculosis must be due to Dr. Norman Tattersall's Association, and his annual report this year is, as always, a welcome exception to the dullness of the average unimaginative summary of local authority work.

We are not surprised to hear that the supply of nurses is the main preoccupation, and the tragedy of 328 beds unoccupied through shortage of staff, compared with 777 patients awaiting admission, must be paralleled in other areas besides Wales. The tuberculosis officers are not any less overworked. New work connected with silicosis and disabled persons, the care of Norwegian seamen and the examination of wartime nursery staffs, are fresh responsibilities added to their normal dispensary work, which goes on, however, with unabated fervour, since over 3,000 more cases were examined at the clinics than in the previous year, while *x*-ray examinations have gone up 25%. New buildings are required—a large hospital near Swansea and up-to-date clinic premises elsewhere. The unification of the Welsh counties in this admirable tuberculosis scheme shows how the needs of a whole area can be planned without disproportionate regard for the natural but inconvenient loyalties of local areas. The Welsh Tuberculosis Scheme is indeed a model which should be studied widely by English counties and county boroughs. The directors of the scheme have naturally been concerned with organization in the future, but their pronouncements are guarded. Probably there will be less need for radical change in Wales than elsewhere, since the principle of unity has been accepted. One would think that this way of regarding the tuberculosis problem as a whole, with preventive and curative methods carried out by the same officers, was its own justification.

Over 60,000 persons have been covered by mass miniature radiography, with the usual 1% of persons with definite pulmonary tuberculosis, or some other chest condition requiring observation. The Welsh National Memorial Association congratulates itself with reason on the mobility of its *x*-ray apparatus, which can apparently examine patients on the side of a mountain with as much speed and convenience as in a mining village. The education of patients in sanatoria is a newly developed feature, and Prof. Davies has been appointed in an advisory capacity to superintend correspondence and study courses. Even in illness Welshmen do not give up their intellectual ambitions. Speaking of thoracic surgery, Dr. Tattersall emphasizes the need for a surgical team in constant practice, and shows that all forms of chest disease can and should be dealt with by the one unit. The scheme in Wales costs about half a million pounds a year, and a thoughtful reader of this report will feel that the public authorities and the community receive value. The presentation of the report itself is a model of the way in which medical schemes should be explained to the public, whose co-operation, both financial and moral, is so essential to their success.

THE NEW QUEEN CHARLOTTE'S

The Queen recently paid a visit to Queen Charlotte's Maternity Hospital, which, its old Marylebone Road days forgotten, is now housed in splendid buildings at Ravenscourt Park in the west of London. Her Majesty inspected in particular the new nurses' home, which anticipates, so far as building and institutional arrangements can do so, the Ministry of Health code on nursing conditions.[1] The Bernhard Baron memorial staff home, which is ultimately to house 135 Queen Charlotte's nurses, is the most modern expression of the endeavour to ensure the comfort and health of the hospital nurse. It includes sitting-rooms, lounges, and a library as yet unfurnished. One innovation is six private rooms for pupils studying for examination or for nurses wishing to write letters or receive visitors, who may be of either sex. The teaching school, with its roomy class-rooms and its wards with dummy patients, is in the same building.

Every nurse has a separate bedroom, attractively furnished, and every sister a bed-sitting room and small dressing-room. Many of the bedrooms have french windows leading out on to balconies or a terrace roof. There is one bathroom for every four nurses. A sunny sick-bay with five windows is provided. The cafetaria-restaurant for the medical and nursing staff is equal to the dining-room of a good-class hotel, and beyond it are ample kitchens for staff and patients; these kitchens are equipped with all kinds of labour-saving devices, and have a system of ventilation so perfect that no smell of cooking penetrates beyond. The patients' food is served from electrically heated chromium-plated trolleys wheeled from the kitchens. The six acres of ground in which the hospital stands grow fruit and vegetables for staff and patients, while 170 hens provide two eggs a week for everyone.

The modern Queen Charlotte's, in which there are between 2,000 and 3,000 confinements a year, has now 135 beds and 123 cots open, its full complement being 200 beds and 175 cots. Its nursing force averages five to every four patients. The main patients' block has an unusual number of delivery suites and large tiled sluice-rooms. No ward has more than six beds, each bed surrounded with cubicle curtains on noiseless rings, and there are many one-bed and two-bed wards. A department for *x*-ray pelvimetry is established. Antenatal, postnatal, and infant clinics are in a separate building, and the oldest parts of the Ravenscourt Park hospital estate are the isolation block and the Baron research laboratories, in which much of the early work on the sulphonamides was done. The hospital and nurses' home, representing an outlay of over half a million, is mainly a wartime construction as yet incomplete, but in scale and provision it bears few marks of wartime stringency.

IMPRESSIONS OF SURGERY IN WEST AFRICA

BY

J. K. WILLSON-PEPPER, M.B., F.R.C.S.

Honorary Assistant Surgeon, York County Hospital; late Temporary Major, R.A.M.C.

It is common knowledge that the West Coast of Africa is no health resort, and on the journey to that land one wondered how these strange surroundings and the equatorial climate would affect the problems of surgery. In this article I have endeavoured to convey my general impressions of the work, and of its background. Siting a hospital in a jungle is no easy task at the best of times, and my efforts to describe as accurately as I can our situation and working conditions should not be interpreted as a veiled criticism of those who had to solve the insoluble.

The hospital to which I was posted was on the fringe of a very large native town just over 100 miles from the coast, in the heart of the thick coastal belt of tropical vegetation. In the early days the " bush " came close to the hospital buildings, and there were as yet extensive undrained swamps on three sides of us—swamps whose ramifications seemed endless and against which we waged ceaseless war. Both they and their air-borne progeny were more than equal to the struggle, and " though men might come and men might go," the mosquitoes went on for ever. Two years after the hospital had opened, a senior visiting medical officer remarked that he had never seen so many mosquitoes gathered together in one place as in the latrines in the officers' lines. These conditions combined to produce the high incidence rate of malaria among our personnel that one would expect.

The hospital was primarily, and at times exclusively, for European troops, so that the following account of the surgical work relates chiefly to Europeans.

During a period of 19 months the total number of cases passing through my hands was very small by comparison with that of surgeons in an active theatre of war, but covered a wide range of surgical problems in climatic conditions far different from those of Europe and North Africa. In my opinion the most important climatic difference was the hot, moist atmosphere which persisted for all but about six weeks in the year, and which favoured the growth of micro-organisms, and indeed of almost any form of life, vegetable or animal. While moulds invaded our books and white ants devoured the woodwork, the staphylococcus seemed to lose all sense of proportion and to spread with the invasiveness of its friend and ally, the haemolytic streptococcus.

There was one other general factor to which I would refer, and that was the ever-present subclinical malaria, which it is reasonable to suppose played some part in altering the normal course of other diseases, whether by flaring up into a full attack, by precipitating blackwater fever, or, in some more obscure way, by influencing the rate of recovery of general health. That this last point is not without scientific support is borne out by the observation that insomnia, general debility, and anaemia frequently remained intractable to any form of treatment other than antimalarial therapy. It was commonly accepted that there was a general falling off of health some time after the lapse of a year and that most Europeans were " run down " after eighteen months, that they became increasingly more susceptible to bacterial infections of all sorts, and that the morbidity rate in non-tropical as well as in tropical diseases was higher among the military personnel than among European civilians. My first feelings were that this was no place for major surgery if it could be avoided—an impression which received ample support from the local civilian European inhabitants, who, if they expressed a view, always seemed to bear this out.

I will now review under a few general headings my impressions of the cases which came under my care, with special emphasis on the differences rather than on the similarities of like problems in Europe. I would like again to emphasize that the patients were European British or Allied soldiers and some civilians, and that Africans are designated as such when mentioned, and to state that I have purposely avoided the mention of figures, which are too small to have any real statistical value.

Wounds

We soon discovered that the surgically inflicted wound, under aseptic conditions, could be expected to heal as cleanly as and even quicker than in a temperate climate. One's confidence mounted by stages, and as a result of increasing experience with relatively safe cases. I have no hesitation now in recommending an exploratory operation on the knee-joint in West Africa, provided full aseptic conditions are obtainable. None of the knee-joints that were operated on in the hospital to which I was posted showed any sign of post-operative infection thoughout my tour, and clean surgical operations such as for hernia ran a course exactly similar to cases at home. With regard to these latter, and to the abdominal cases, the only noteworthy difference was the absence of post-operative chest complications. This was especially noteworthy as it included some severe upper abdominal operations.

The general impression was that clean surgical wounds, such as I have described, did best if lightly dressed with gauze to allow the maximum evaporation of moisture from the skin surface, and it was our usual custom to fix the dressing at either end with strapping, and to avoid the use of wool and bandage or anything approaching an occlusive dressing.

We formed the impression that contaminated wounds could be expected to run a parallel course to those in Europe, but it should be emphasized that we had no penicillin and no sulphathiazole, and that, therefore, results could not be expected to compare with more recent ones. Heavily infected wounds, on the other hand, were a very different proposition indeed. Where it had been possible to treat a clean penetrating revolver bullet wound of the ankle-joint, with much shattering of bone, in a closed plaster cast with excellent results, we found all attempts to treat heavily infected wounds by occlusive methods a total failure. So far as my experience went Winnett Orr's or Trueta's methods were a total failure in the area of West Africa where I worked. Whether one used plaster-of-Paris, elastoplast, or any other improvised method, whether one changed the dressing frequently or at longer intervals, the result seemed to be always the same—the sepsis tended to be deeper, the pus more profuse, and the evidence of healing non-existent. This state of affairs set a nice problem in the treatment of septic compound fractures, which fortunately were few.

In the great majority of cases the predominant organism was the *Staphylococcus aureus*, which seemed, as I have already stated, to take on the invasive and septicaemic tendencies of the haemolytic streptococcus. A certain number of infected wounds and ulcers grew a mixture of organisms, but my impression was that in the great majority of cases the *Staphylococcus aureus* quickly overgrew the others.

In the absence of penicillin and sulphathiazole, we found the best local treatment of such wounds was immobilization, free drainage, and frequent hypertonic saline or eusol dressings. Most of these cases could be quickly brought under control by such methods, though I was completely defeated by a septic ulcer below the inner malleolus in an officer, which was still pouring pus after four months in spite of every resource at my disposal having been tried.

As the staphylococcus was the predominant organism we did not get, or expect to get, much success with oral sulphonamides or sulphapyridine, and we gave up using them in cases where the tendency for infection to spread had been arrested.

I did not see a case of gas gangrene or tetanus in either a European or an African.

Inflammatory Conditions

Mention has already been made of the tendency for staphylococcal infections of the skin to spread. The incidence of boils and carbuncles was high, especially in men towards the end of their tour, and the tendency for cellulitis to develop from what was originally a localized staphylococcal lesion was very marked. In my experience a streptococcus was rarely obtained by culture, though clinically one would have expected it frequently. The incidence of staphylococcal lesions in the deeper parts of the body seemed to me to be far greater than at home and on a par with those of the skin. Staphylococcal septicaemia, empyema thoracis, frontal sinusitis, and urethritis were noteworthy among them.

The case of frontal sinusitis, which occurred in a young airman, took a sinister course, starting quietly and ending in three months in death.

Staphylococcal urethritis was frequent and extremely intractable, and staphylococcal infections of the external genitalia, on one occasion associated with superficial gangrene, were not uncommon. It seemed to me that there was an abnormally high incidence of perianal suppuration such as ischio-rectal abscess and fistula formation. I did not have a case of intramuscular abscess of unknown origin in a European, so often seen in the African. Infections of the hand were common, but I had a case in an African of tenosynovitis of the finger due to monilia in pure culture, which is described, but is, I believe, extremely rare. Chronic suppurative conditions did badly in West Africa, and in fact any chronic inflammatory lesion tended to get worse, and attempts to heal such cases there frequently failed.

Tropical ulcer without the characteristic spirochaete may not be the genuine article, but I can only say that a large ulcer, occurring almost always below knee level, and following slight trauma, occurred frequently among British troops, and never once did we find the characteristic organism described in textbooks. The ulcer formed rapidly, after the breakdown of a local patch of cellulitis with intense but localized engorgement of vessels, and took months to heal. The organism we found in almost every case was the *Staphylococcus aureus*. Had we at that time had penicillin powder available I think we could have cured the cases in a matter of days. We tried everything from closed plaster-of-Paris casts to fresh air in the air-conditioned room, to shorten the period in hospital. Some surgeons had successes in African cases by skin grafting, but I must admit that my skin grafts suffered the fate of all lesions under a thick dressing, for they were floated off in a sea of pus. It may well be that my technique was at fault, and that 48-hour dressings would have saved them. At all events, what had sufficed for success in Europe I found was a total failure in West Africa. Neither did I find insufflation with any sulphonamide preparation then available to be of the slightest use, as the powder formed a thick crust with the discharges, and suppuration went steadily ahead underneath. We found that the air-conditioned room, which was drier, cooler, and insect-proof, was probably the most efficacious treatment, and after that Capt. Henry Foster's method of directing a current of air at the lesion from an electric fan. Hypertonic saline dressings frequently applied came third, and at the bottom of the list a closed plaster cast or other form of occlusive dressing, than which nothing could have been worse.

Acute appendicitis occurred among Europeans in about the same proportion as in Europe, but I personally did not come across a genuine case in an African. Among my cases I noted two points: a relatively high proportion of gangrenous and perforated appendices, and a tendency for really acute appendicitis to be associated with diarrhoea. This latter symptom was not by any means invariably associated with pelvic peritonitis or pelvic abscess, and must either remain unexplained or be regarded as a freak observation. It is not unreasonable to suppose that, with the higher incidence rate of bacterial and parasitic diseases of the intestine in tropical countries, the appendix on becoming involved does not arrest the excessive peristalsis of the irritated large bowel.

Fractures

During my tour of service I was called upon to survey the case records of all our fractures, as it had been reported that there was a relatively high incidence of delayed union in certain hospitals on the Coast. Among the European patients I did not find any evidence of this, but it was noted that skiagrams of the bones of European British and Allied troops showed relatively denser calcification than was the case in Africans, and I think it is probable that hospitals treating African troops only might well have had a higher percentage of delayed union. On looking back, I think now that both British and African cases showed a smaller quantity of callus than one is accustomed to see some weeks after injury, which would suggest that there might have been some degree of vitamin C deficiency.

Closed fractures were treated in exactly the same way as in Europe—usually by immobilization in closed plaster-of-Paris after reduction, and with satisfactory results. In spite of the climate we treated three cases of fractured spine in complete hyperextension plasters, in which the occupants walked about freely and without showing signs of heat-stroke. We took the precaution of cutting a window over the abdomen with this in mind.

At this point it may well be asked why serious cases of all types, and those becoming chronic, were not sent back to England rather than retained in West Africa under adverse climatic conditions. The explanation is that the shipping situation was at that time so bad that it took weeks, and often months, before serious cases could be moved, as they had to travel in an escorted ship. The only policy that could be followed was to treat all cases on definitive lines, and to transfer to England the more urgent ones whenever possible.

Tropical Diseases

Among the Europeans I found surgical conditions due to tropical diseases extremely uncommon. I searched in vain for bilharzia of the bladder and for an amoebic abscess of the liver. Both these conditions were frequent enough in African troops, who also could often produce guinea-worms out of their legs, and occasionally loa-loa worms out of their conjunctivae, amidst great excitement and much hasty sterilization of ophthalmic instruments. Usually by the time we were ready the worm had passed on, and we had the forlorn pleasure of demonstrating to the excited onlookers where it had been five minutes before.

But about amoebic infections of the lower bowel I would emphasize, at the risk of being thought tedious, the following points: That we had numerous instances in which examination of the stools for *Entamoeba histolytica* had failed repeatedly and over a period of months, during which time the patient's health had steadily deteriorated, but that on passing a proctoscope typical amoebic ulceration was immediately seen, and a direct smear from an ulcer with a platinum loop revealed the organism in large numbers. In my experience of this disease, if ulceration does not come within the range of the proctoscope it is very unlikely to come within that of a sigmoidoscope, which probably means it is not there at all. Provided certain elementary rules are observed, the chances of an immediate and accurate diagnosis with this simple and safe instrument are extremely high. The rules are these:

(1) Don't give any form of treatment to the patient for 48 hours before examination, especially any rectal lavage.

(2) Don't use a proctoscope which has been dipped in any antiseptic, as the amoebae immediately "freeze up."

(3) Have the pathologist at your elbow when you take the specimen, so that it is immediately mounted in warm saline and examined without delay.

Rare Diseases

I saw three cases, all in Africans, which I think worthy of mention.

The first was a case I have already mentioned of a monilia infection of the tendon sheath of a finger in an African corporal. The history was of five days' pain, stiffness, and swelling in the finger, which had an old deformity due to a boxing injury five years before. Clinically the finger suggested a tendon-sheath infection, but of such mild degree that for 24 hours I was in some doubt as to the diagnosis. There was no sign of infection round the root of the nail or elsewhere on the hand, and no past history of infection. On incising the tendon sheath a pearly opalescent fluid came out, which was investigated bacteriologically and found to contain the fungus mentioned, in pure culture. Unlike bacterial sheath infections, there was a return to full function.

The second was in an African boy of 8 years, who had a massive osteoma growing from the horizontal and ascending ramus of his lower jaw, chiefly from the outer aspect. But it extended downwards into the neck and upwards inside the malar arch, displacing the latter outwards. There was a long history of gradually increasing deformity. Dr. Garrett, of the Colonial Medical Service, who was in charge of the case, asked me for my opinion as to treatment, and we decided that an attempt should be made to remove the bony mass after ligation of the external carotid artery. At operation I found I was unable to reach this vessel on account of the downward extension of the tumour, and was obliged to ligate the common carotid instead. The bony mass was then chiselled away piecemeal from the outer aspect of the mandible in a relatively bloodless field. There was no resultant hemiplegia following the ligature of the vessel, but the cosmetic result was to some extent spoilt by the distortion of the malar arch. The bony mass arose from practically the whole of the outer aspect of one side of the mandible and was a mixture of cancellous and ivory bone. There was no evidence of malignant change.

The third was that of a female child of 3 years, with a circumscribed mass in the abdomen about the size of a large grapefruit, which was shown to me by Dr. Northrop, of the American Baptist Mission Hospital at Ogbomosho. There was no clinical indication as to what this might be, and we decided to do a laparotomy. We found a circumscribed tumour of the size of a grapefruit in the substance of the liver, which appeared to have no metastases nor to be attached to any other structure, and which shelled out surprisingly easily. The child unfortunately died on the tenth day after operation. The tumour, which I reported on in more detail in the *Journal of the R.A.M.C.* of July, 1944, has been the subject of much discussion, but no definite opinion has been given as to its nature, though Major Janet Niven, R.A.M.C., expressed the view that it was probably a case of congenital cystic disease arising from bile-duct epithelium.

Some General Observations

Along the coastal belt of parts of West Africa there is stated to be a layer of vapour approximately 10,000 feet in depth, which to a large extent filters off the ultra-violet rays before they can reach the surface of the earth. Whatever the precise physical phenomena may be, it is certainly true that the skin tans unwillingly, and that many people who lead a comparatively open-air life look pale and washed out. I do not know to what extent this may affect the general health of Europeans, but assiduous sun-bathing does eventually produce tanning of the skin, and it seemed to me that latterly, when a greater proportion of men were sun-bathing fairly regularly, there was a rise in the general standard of health. But, as I have already said, other factors were also at work. It seems hardly possible in a land of green vegetation and many varieties of fruit that there could be serious vitamin A or C deficiencies, but the filtration of the sun's rays by vapour may have had some effect on man and vegetation alike. On this subject I feel I am on dangerous ground, but at all events the possibility of vitamin deficiency in tropical ulcer, gingivitis, prolonged sepsis, and broken-down wounds was not forgotten, and extra vitamins in big doses were given in many cases; but I confess that I never felt that this line of therapy appeared to affect the progress of the cases materially.

In regard to haemorrhage during operations, I think that there was rather more at times than one would expect in most cases in Europe, but I was never faced with uncontrollable bleeding in the course of any operation I performed.

Papillomata of the skin anywhere, but especially of the genitals, seemed to thrive in West Africa, and to seed themselves with alarming rapidity. I never saw one on the penis of a circumcised patient, and soon learned that circumcision was the only treatment holding out any prospect of cure.

Owing to the kindness of medical friends who were in charge of the civil population, I had opportunities of seeing many curious conditions in Africans and of operating on a number of them. I formed the opinion that the average African was less susceptible to surgical shock than a European, and that the degree of haemorrhage during an operation was comparable with that of a European in Europe.

Conclusion

I have written these impressions of surgery in West Africa from the point of view of a surgeon whose whole training and past experience have been in Europe, in the hope that they may have some general interest. My experience of the African is much more limited than that of many of my contemporaries on the Coast, but I had opportunities of treating a larger proportion of European British and Allied patients there than most surgeons, and on these I have largely based this article. As a result of ceaseless effort in many directions the unsatisfactory conditions in which we worked in the early days were, by the time I left, largely remedied, and the general health of our personnel had greatly improved.

I am deeply grateful to all my colleagues in the Army, in the Colonial Medical Service, and elsewhere for their friendship, their collaboration, and their generous hospitality.

MEDICAL SCIENCE IN RUSSIA

The following account of the work of the recent session of the Academy of Medical Sciences, U.S.S.R., has been sent to us from Moscow by Academician V. Parin, the general secretary.

Connecting Theory and Practice

The second session of the Academy of Medical Sciences, held in Moscow between Oct. 28 and Nov. 2, summed up results of the organizational period of the Academy and its institutes. The session outlined the tasks confronting the Academy in connexion with the new five-year plan that is now being drawn up: that in the field of public health services calls for complete restoration of all medical institutions wrecked in Nazi-ravaged districts and for further improvement of medical assistance in the service of the population of the U.S.S.R.

A characteristic feature of this session was the desire shown by all its participants to connect theory still more closely with practice. During the war medical men of the Soviet Union achieved outstanding successes in treatment of the wounded and in protecting the health of the population. These attainments were a result of the selfless work of medical personnel and of the introduction into practice of new or perfected medical preparations and methods of treatment.

Academician A. Bogomolotes and others who took part in the discussions spoke of the necessity for including certain long-term research problems in plans for research institutes which may serve as a base for important future medical discoveries. All the speakers mentioned the achievements of medical science in Europe and in the U.S.A., particularly the study of nutrition and dietetics in the latter country, and expressed great interest in foreign equipment and in the foreign scientific press. It was noted that institutes associated with the Academy had in the course of ten months carried out comprehensive research work giving highly satisfactory results. Methods for improving the efficacy of penicillin had been worked out in the Institute of Neurosurgery, under the direction of Academician N. Burdenko. An expedition from the Institute of Neurology, headed by Prof. Chumakov, had studied a hitherto unknown virus disease—Crimean haemorrhagic fever—and discovered methods for combating it. Interesting experiments had been made in the Institute of Haematology and Blood Transfusion. The importance was stressed of collaboration between representatives of various departments and institutes of the Academy.

A Five-year Plan for Research

Prospects for the development of the Academy of Medical Sciences during the five-year period 1946–50 were discussed in detail. The following are the chief scientific problems around which the work of research institutes and departments of the Academy is to centre in the immediate future: more efficient methods for combating infectious and parasite-borne diseases, cancer, and tuberculosis; study and elimination of traces left by the war on public and individual health; further improvement in maternity and child welfare measures; study of nutrition and dietetics and the reactivity of the human organism.

The session elected an additional number of new members and corresponding members of the Academy. Medical organizations of the country had nominated 65 candidates, whose scientific activities were thoroughly considered by special commissions formed in all departments of the Academy; 39 new members were elected into the Academy by secret ballot.

BRISTOL HOSPITALS PROVIDENT FUND

The Bristol Hospitals Provident Fund, through which persons of moderate means may obtain grants towards the cost of specialist fees, surgical operations, and hospital and nursing-home treatment, has now a total membership exceeding 58,000. It was recently decided, having regard to the increase in cost of hospital maintenance, that the rate of contribution to the fund should be raised from 3d. to 4d. a week. In 1944 over £25,000, or 40% of the fund's total distribution, was paid towards the cost of services rendered by the hospitals to the contributors and their dependants; of the remainder, 29% was on account of services to members of other contributory funds with which there are reciprocal agreements, and 31% was distributed in the form of grants for specified or unspecified purposes. The fund has made a number of agreements with municipal and county authorities under which contributors are exempt from inquiry into their means and payments are accepted by the authorities from the fund in full settlement. In 1944 it was agreed to abolish the income limits of £4, £5, and £6 a week according to family responsibilities in favour of the new National Health Insurance limit of £420 a year irrespective of number of dependants, on condition that the medical staffs of hospitals receive a percentage of contributory scheme grants for services rendered.

Reports of Societies

PROTEIN METABOLISM

A meeting of the Scottish Group of the Nutrition Society was held in the Rowett Institute, Aberdeen, on Oct. 20, under the chairmanship of Dr. D. P. CUTHBERTSON.

In opening the meeting Dr. Cuthbertson gave a historical survey of protein metabolism and emphasized certain points. He recalled that when animal proteins were short the dietary proteins might economically be supplemented by soya bean and similar foods. That being so, the old terms first- and second-class protein as applied to mixtures of food proteins became meaningless and should be discarded. The protein intake had been shown to be important in relation to resistance to disease. Protein depletion decreased the capacity to form antibodies, and this rapidly improved when high-quality protein was available. Physical trauma appeared to induce a phase of vigorous protein katabolism, which might be largely controlled by the addition of methionine to the diet.

Essential Amino-acids

Dr. C. P. STEWART (Edinburgh) said that by common consent the term "essential amino-acid" was restricted to those which an animal could not synthesize from ammonia or non-nitrogenous substances, though some restricted the term still further to those which the animal could not synthesize in sufficient quantity to promote normal growth. For the growing rat the ten essentials were threonine, valine, isoleucine, leucine, methionine, lysine, phenylalanine, arginine, histidine, and tryptophan. Requirements for maintenance of the adult animal might be different. In the case of adult rodents arginine could be dispensed with. In man certain experiments had thrown some doubt on the necessity for histidine. Under normal conditions there was some evidence that amino-acids not ordinarily needed in the diet, like cystine, might become indispensable. In certain cases, apparently, the natural amino-acid might be replaced by the corresponding keto- or hydroxy-acid, the N-acetyl or the N-formyl derivative.

Amino-acids were undoubtedly used for other purposes than the manufacture of proteins. Histidine would seem to be utilized as a precursor of purines and for the formation of histamine. Phenylalanine could give rise to adrenaline, thyroxine, and tyrosine, and possibly melanin. Methionine was concerned with the formation of creatine and of cysteine. Special functions had not yet been discovered for certain amino-acids. In general, lack of an essential amino-acid produced no definite specific symptoms such as were associated with the vitamin deficiencies.

Mr. H. D. GRIFFITH (Aberdeen) described the use of isotope tracers in the study of protein metabolism. Stable isotopes of hydrogen, carbon, nitrogen, and sulphur and radio-active forms of carbon, sulphur, and phosphorus were available. Radio-active isotopes could be followed in metabolic processes much more readily than stable isotopes. Nitrogen and carbon were particularly valuable in tracer research.

Modern Methods

Dr. J. N. DAVIDSON (Hampstead) discussed modern methods of studying protein metabolism. He pointed out that the most important advance of recent years had been the use of isotopes for following metabolic pathways. Nitrogen N^{15}, Sulphur^{31}, and Deuterium C^{13} had been used in this way. Heavy nitrogen, for example, could be introduced in the synthesis of amino-acids, and these labelled amino-acids could be traced in the tissues and in the excreta. Curiously enough only a fraction of the special nitrogen appeared in the urine as labelled urea, the rest being distributed throughout the body, even in such inert tissues as skin and tendon; and in the body the labelled nitrogen was found not only in the amino-acid fed to the animal but also in other amino-acids. From this it was inferred that the nitrogen of any amino-acid could be rapidly and easily transferred to others and that the tissue proteins were in a constant state of flux, forming a sort of general metabolic pool. If this was so, then the terms "exogenous" and "endogenous" metabolism ceased to have any precise meaning. By introducing both labelled nitrogen and carbon into an amino-acid more details could be obtained. Certain amino-acids could readily change the amino group, but their carbon chain was indispensable and could not be built up by the body. The behaviour of lysine was rather different, for both carbon chain and amino group were indispensable as a single unit. Since lysine did not take up nitrogen from other amino-acids it could be used as a means of labelling proteins, and this had been employed in the study of shock. By such methods useful information could also be obtained about the metabolism of methionine and nucleoproteins.

Dr. A. B. ANDERSON (Glasgow) discussed the therapeutic use of protein hydrolysates, and gave an account of his experience of their administration. He concluded that intravenous alimentation appeared to be of most value in cases of burns and in patients before and after operation. Hydrolysate therapy had no special advantage in starvation and in the gastro-enteritis of infants. Casein digests by mouth had the disadvantage of unpalatability, and for oral administration meat digests were preferable.

Medico-Legal

INSULIN AND THE MOTORIST

In an attempt to deal with the problem of the drunken and drug-addicted motorist, Parliament enacted in the Road Traffic Act, 1930, that it should be an offence for anyone to drive a car while under the influence of drink or drugs to such an extent as to be incapable of having proper control of the vehicle. The drugs in the contemplation of Parliament were obviously more or less identical with those controlled by the Dangerous Drugs Acts—chiefly morphine and cocaine—and it is highly doubtful whether any legislator who approved the passage of the Bill foresaw that one day a diabetic motorist would be charged with driving under the influence of insulin. This, however, happened earlier in the year at Bournemouth,* where the magistrates convicted a driver, fined him £2 and costs, and suspended his licence for a year. He had collided with a van and been found partially helpless and incoherent. There was no dispute that he was a diabetic and had had too much insulin and insufficient carbohydrate with his midday meal. His own story was that he depended on his car to carry out his duties; on the day of the accident he did not have his normal midday diet; during the afternoon he felt a tingling in his fingers and took a lump of sugar, and later he felt tired and decided to drive home; he thought he drove perfectly normally, but could not remember the accident. On his appeal to Quarter Sessions, his counsel advanced the ingenious argument that there was no proof of the unlawful influence of a drug. The motorist, he said, was right to take insulin to restore himself to normal health on medical advice, and he was under the influence, not of the drug, but of too little food. Medical men, however, gave evidence that insulin is a drug in the medical sense of the word, and the Recorder, Mr. H. D. Samuels, held that it was a drug within the meaning of the Act and that the motorist had been rightly convicted. On the other hand, as the appellant was entirely blameless in the matter and did not deserve to be punished, he dismissed the case under the Probation of Offenders Act and restored the licence, but left each side to pay its own costs. The decision is not binding on another court, and any bench of magistrates may still hold that insulin is not a drug for this purpose; but it is rather difficult to avoid the conclusion to which the Recorder of Bournemouth came.

---

* *Bournemouth Daily Echo*, June 26.

Dr. W. Essex Wynter, consulting physician to Middlesex Hospital, who died on Jan. 4, bequeathed all his real estate at Newbury to Middlesex Hospital for use as a home for retired and pensioned sisters and nurses or convalescent sisters and nurses, and his household effects, etc., and also £7,500 upon trust for the upkeep thereof. A full account of the very ancient building within the curtilage of Bartholomew Manor which Dr. Wynter bought and restored was given in the *Journal* of Feb. 19, 1938.

Correspondence

The Operation for Varicose Veins

SIR,—I have read Mr. Harold Dodd's letter on the operation for varicose veins (Oct. 13, p. 510). May I be permitted to record a few of my own observations in regard to the treatment and operative procedure for varicose veins.

1. It is my opinion that in all cases where the valves of saphenous veins are proven to be incompetent and accompanied by multiple varicosities of the leg, ligation and excision is the operation of choice.

2. Inasmuch as the anatomy of the venous system is variable a thorough search should be made in the groin incision in order to ligate tributaries—e.g., superficial external pudendal, superficial epigastric, superficial circumflex iliac, and other nameless tributaries which may or may not be present. Two or three inches below the fossa ovalis the saphenous vein will often be seen to be joined by two or three large venous branches—e.g., the external femoral, middle and internal femoral tributaries of the great saphenous. At operations for recurrence of varicosities I have noted that these veins appear to be markedly dilated, due to the fact that they were not ligated and sectioned at the time of the original operation.

3. Prior to operation a series of tourniquets from the thigh to lower leg should be applied while the patient is lying down and his leg elevated in order to empty the venous system. The patient is then allowed to stand and walk and the tourniquets are removed starting from below upwards. Areas of incompetence due to the communication tributaries from the deep to the superficial system are discovered. These areas are then marked out with indian ink in order to facilitate the operative procedure.

4. Certainly the saphenous vein should always be ligated in the groin, but it is my opinion that many unsightly ankle scars can be avoided if ankle ligations are reserved for the very infrequent cases which would require this procedure. The secondary sites of ligature depend on the site of gross venous incompetence, as shown by the tourniquet test. There are several cases which require only a high saphenous ligation, but where there are "blow-outs," sites of gross incompetence, these must also be ligated and sectioned to obtain good results. De Takats (1933) claims that high saphenous ligation alone will result in a direct cure in 20% of the cases. High ligation followed by injection produces excellent results and diminishes the incidence of pulmonary emboli.

I have found that injection at the time of operation lengthens convalescence because of delayed healing at the operative site and pain in the extremity involved. I prefer to do a high saphenous ligation alone, or combined with multiple ligations depending on the individual case. Both ends of the saphenous should be doubly ligated and transfixed. The patient is allowed to go home on the day following operation. Six days later the sutures are removed and, if necessary, injections are started. For injection therapy it has been my practice to use 5% sodium morrhuate solution or a product called "sylnasol"—sodium psylliate in 2% benzyl alcohol. It has been our experience that patients treated by these methods have been able to return to work with a minimum loss of time and wages, with obvious advantages to themselves and their families.—I am, etc.,

Treatment of Varicose Ulcers

SIR,—I had not been long in general practice before I realized how tedious it was to get chronic varicose ulcers to heal. It is interesting to review the various methods one has used in the past. My earliest recollections are those of seeing "elastoplast" used for varying lengths of time. The bandage was removed after, say, a week or ten days, sometimes perforce earlier, because of its sodden and always offensive condition, only to be replaced with a fresh bandage; and this went on for weeks on end. Healing took months. The next trial was that of "viscopaste" bandage and similar absorbent preparations, the idea being for the bandage material to absorb any discharge or eczematous matter. I found this type of bandage little or no advance on the last. Incidentally I well remember a case where I incorporated an ulcer in a plaster-of-Paris bandage (taking a tremendous risk) when treating a fracture, with perfect results on removal of the plaster.

My next efforts consisted in making an ointment of zinc oxide and white vaseline and covering the ulcer with strips of lint c̄ paste. I found that whereas this was soothing it did not promote healing or absorb the eczematous fluid, nor did the wound remain sweet. This led me to try another modification of zinc oxide with olive oil, with a touch of scarlet-red ointment. This gave better results for a few cases.

In an endeavour to improve on this preparation—for some skins were sensitive to scarlet red—I used cod-liver oil and sulphanilamide powder, occasionally (usually after trial) in combination with a little scarlet red. Healing with this preparation was quicker; the wound was clean; but I failed to dispose of or absorb the eczematous fluids. Repair still took weeks. This, then, led me to discard oily preparations, and for the past eighteen months I have been using pulv. lapis calamin. with gentian-violet powder and solution made into a mauve paste of the consistency of putty. This paste was spread on the ulcer with a knife in an endeavour literally to fill it and to level off at the edges. In a couple of hours this would dry and possibly crack in a few places. A simple dry dressing would be put over the paste to keep it in position. Patients were taught and instructed that when cracks appeared or where there was an oozing of sero-sanguineous fluid they were to apply a fresh layer of paste, allow to dry, and cover. This process of applying a fresh layer was repeated by the patient as often as cracks developed or matter oozed from the edges or little pieces of paste fell out.

In two or three weeks' time a hard, dry, mauve, wart-like crustation would form over the ulcer; and this was not removed. It would fall off in due course, leaving a healed smooth shining surface level with the rest of the skin. Occasionally curiosity on the part of patient and attendant would lead to removal of this mass to see what was happening underneath. This naturally prolonged the time of healing; and, of course, the ulcer had to receive fresh applications of the paste till the dry stage was reached. To this paste I have at times added sulphanilamide powder, especially for dirty ulcers, but sulphanilamide should *never* be applied to a deep ulcer, as it only increases the flow of sero-sanguineous offensive exudate. This last method has rarely failed to effect a healing, even though slow and drawn out a bit. But its main advantage was that the patient could carry out the necessary instructions after a couple of simple demonstrations. There have been occasions where the skin for several inches surrounding the ulcers was red, with a dry scaly eczema. Using the gentian paste for the ulcer *alone*, I have applied another preparation of castor oil, pulv. lapis calamin., a trace of tar, and salicylic acid, to the dry eczema, with gratifying results. Care, however, must be taken to see that the oily tar paste does not merge into the ulcer, for it will not mix with the gentian paste and healing will be retarded.

I have no figures and no lengthy detailed notes of individual cases, and I think they would serve no purpose. In a small practice with a limited number of cases such things as controls and day-to-day notes are not possible, but the above methods have been tried out, each in turn, for a fair number of cases over a period of thirteen years.

I next come to my latest venture—namely, the use of penicillin cream. Through the courtesy of the Department of Preventive Medicine, Bristol University, I have been given a small quantity (strength 400 Oxford units per g.). I have had four cases (one a woman whose ulcers have been in existence for twenty years) of varying degrees of ulceration. My results so far have been most encouraging. Two cases have completely healed. Two will require at the most two further applications, when the ulcers should have filled in with granulation tissue and levelled off with the skin. In all four cases healing has been very rapid as compared with earlier methods: where formerly it was months, now it is weeks.

May I advise any who may be interested to try this latest method that the cream should be applied thinly over the raw surface of the ulcer, paying particular attention to the edges. Thick applications of cream are a waste of so precious a commodity. Furthermore, too frequent changes of dressings are, in my opinion, harmful and wasteful. On an average a fresh dressing with fresh application of cream should not be oftener than once a week.

In conclusion, with all methods (including the use of penicillin) repeated elevation of the limbs every day for a couple of hours at a time is necessary.—I am, etc.,

Chipping Sodbury, Glos. ROSS. K. BROOKS.

Morphine as a Prophylactic for Ileus

SIR,—In reply to Mr. Judson Chesterman's letter (Nov. 24, p. 740), is it not unnecessary to look at recent work to discover what is the effect of morphine on the movement of the intestinal contents? We all know that pil. plumb. c̄ opio *B.P.C.*, pulv. cret. aromat. c̄ opio *B.P.*, pulv. kino. co. *B.P.C.*, etc., are preparations in which opium is used to check diarrhoea.

The precise effect of morphine on the intestine has been studied by many workers, including those mentioned by Mr. Chesterman. A detailed account of all this work, including a critical summary, is given in Supplement No. 165 to the *Public Health Reports* of the United States Public Health Service. This most valuable publication on the *Pharmacology of the Alkaloids* is written by Krueger, Eddy, and Sumwalt, who have themselves studied the action of morphine on the intestine. They discuss the different methods which have been used to examine the action of morphine on the intestine and emphasize what has been pointed out by earlier workers, that these methods often make it impossible to draw conclusions about the joint effect of increased tone, increased segmentation movements, and changes in peristalsis on the propulsion of intestinal contents. They say:

> "The most satisfactory contribution to the subject of the effect of morphine on the peristalsis of the small intestine has been made by Quigley, Highstone, and Ivy (*J. Pharmacol.*, 1934, **51**, 308). They made determinations of the interval required for the passage of a bolus through a Thiry-Vella loop, the bolus being immediately reinserted and its propulsive rate redetermined. Following 0.5 mg. of morphine per kg., intestinal propulsive activity of the ileum was increased 30 or 40% for about 30 minutes and was followed by a secondary rapidly developing decrease in propulsive activity. . . .
>
> "The bolus method showed an abrupt and pronounced decrease in propulsive activity beginning 30 minutes after the injection, at a time when balloon records indicated augmented peristaltic activity. Thus it was evident that the tracings obtained by the balloon method cannot be directly translated into terms of propulsive efficiency. The period of reduced propulsive activity, which is really the outstanding effect of morphine, must play an important role in the well-known constipating action of this drug."

Krueger, Eddy, and Sumwalt have calculated the reduction in propulsive activity from the data of Quigley, Highstone, and Ivy. They find that after 0.5 mg. morphine per kg. (which is equivalent to 0.5 grain for a man of 60 kg.) a bolus moves in 4 hours about 80 cm., whereas before this dose of morphine it moved 300 cm. Thus, although there is an initial quickening of propulsion, the main effect of morphine is to produce fourfold delay.

Mr. Chesterman says that "morphine produces a long-lasting increase of intestinal tone unassociated with spasm in both the small and the large intestine." Both Thomas (*Proc. Soc. exp. Biol.*, N.Y., 1926, **23**, 748) and Schroeder (*Arch. exp. Path. Pharmakol.*, 1933, **170**, 359) are definite that morphine causes spasm of the pylorus. Spasm of the lower part of the bile duct has been shown to follow the injection of morphine and to cause a rise in intrabiliary pressure in man from below 20 mm. water to above 200 mm. (Butsch, McGowan, and Walters, *Surg. Gynec. Obstet.*. 1936, **63**, 451). Observations that morphine causes increased tone and spasm of the sphincter of the bladder date back to 1828, when it was first described by Bally. It would be surprising, in view of this widespread spasm-producing action, if the small and the large intestine were exempt, and Schroeder (loc. cit.) observed that morphine produced a contraction of the ileo-colic sphincter.

In view of these considerations, surely there is no justification for the use of morphine as a prophylactic against ileus! No evidence in which control observations were made during an earlier period can modify this conclusion. It is surely impossible to say afterwards that there has been no change in the readiness with which the operation of Caesarean section has been undertaken. If in the earlier period the operation was more often undertaken late in labour, when the patient was suffering from some exhaustion, the results observed would be explained.

With regard to the parasympathomimetic drug physostigmine, which, by preserving the acetylcholine formed in the gut wall, increases intestinal movements through the natural mechanism, it is important to remember the great variation which exists in individuals towards any drug. It is necessary to find the right dose, and, if nausea and colic occur, too large a dose has been given. Repeated small doses should be used of a freshly prepared solution. The *B.P.* dose is 1/100 to 1/50 grain, and it is probably wise to begin with 1/200 grain; a second dose can then be given after 30 minutes.—I am, etc.,

Department of Pharmacology, Oxford. J. H. BURN.

Sequelae of Emphysematous Lung

SIR,—Dr. Ronald Jones has described in the *Journal* (Oct. 20, p. 530) two cases of massive surgical emphysema, pneumothorax, and pneumomediastinum associated with bronchoscopy, and these were discussed in an interesting letter by Dr. J. E. Bannen (Nov. 10, p. 665).

Cases of pneumomediastinum followed by interstitial emphysema of the tissues of the face, neck, and trunk have been described occurring spontaneously in association with a variety of conditions—e.g., the exertions of labour (Nussbaum was able to add twelve cases to the 130 Gordan collected, while Phillips had a remarkable series of five personal cases in four years); phthisical haemoptysis (Bryan); asthma (L. and J. Rosenberg reviewed eighteen cases in 1938 and I have had one personal case not yet described); whooping-cough (Beaumont); exposure to depth charges (Cameron, Short, and Wakeley), etc., as well as being produced traumatically in association with such operative procedures as tracheotomy, lobectomy, and bronchoscopy.

Although, as Bannen suggests, vesicular emphysema is usually present when this condition arises, yet it is not invariably so, as *x*-ray examination of the chest in Phillips's five cases failed to demonstrate its presence. In fact, if vesicular emphysema were a necessary precursor, one would expect to find, in view of the number of cases of pneumomediastinum occurring during labour, puerperal emphysema, a condition not so far described, of common occurrence. C. C. Macklin, however, showed experimentally that vesicular emphysema was not essential before pneumomediastinum could be produced. He produced it by over-infiltrating part of a normal healthy lung of an anaesthetized cat. He showed that it was due to a break through the alveolar base into the perivascular sheath, along which the air passed to the mediastinal wall, and, when pressure was sufficient, this wall ruptured to give pneumomediastinum.

With regard to treatment, it is well to remember that this alarming-looking condition of marked subcutaneous interstitial emphysema usually calls for no treatment *per se*, and that it will entirely disappear in the course of a few days. Heroic incisions are not necessary. The exception is the very rare condition of "pressure pneumomediastinum," shown by marked dilatation of the veins of the neck, in which case all that is required, as M. T. Macklin pointed out, is the insertion of a hollow needle into the mediastinum at the side of the sternum, or the insertion of a catheter into the base of the neck and pushing it down to the site of the encapsulated air. Hamilton Bailey suggests that it may be necessary to incise in the neck down to the trachea and provide some sort of suction apparatus, quoting Tiegel's case. However, it is difficult to know why it should be necessary to "suck" out air that is under pressure. Thus in Jones's two cases air failed to escape although needles were inserted into the mediastinum, and although in one case suction was applied. This would seem to bear out the contention that in the majority of cases this treatment is unnecessary. The cyanosis must have been due to the blockage of the respiratory tracts by the swollen mucosa he describes, and not due to "pressure pneumomediastinum," and the rapid reintroduction of the bronchoscope and other measures of resuscitation undertaken undoubtedly saved the patient's life.

Bannen's sign for the diagnosis of pneumoperitoneum is surprising and the reverse of what one would have imagined—i.e., one would have thought that the intraperitoneal gas would have risen and not sunk to the most dependent part.—I am, etc.,

Non-specific Mesenteric Lymphadenitis

Sir,—I cannot help writing to congratulate Mr. Ian Aird on his excellent and timely article on acute non-specific mesenteric lymphadenitis (Nov. 17, p. 680). During the last few years I have come across two definite cases of this condition, and, feeling that I should like to know more of the pathology, etc., I have been disappointed to find how little is mentioned of acute abdominal lymphadenitis in the textbooks. For this reason I think we owe a debt of gratitude to Mr. Aird.

The first case which I saw and was able to label a non-specific lymphadenitis occurred when I was called to a fever hospital to operate on a child with scarlet fever, and diagnosed as suffering from an acute appendicitis. On performing a laparotomy the appendix was found to be normal, but the mesentery of the bowel contained masses of enlarged lymphatic glands. These were round and elastic in consistency, as described by Mr. Aird.

The second case, which was more recent, was in a lady medical officer in the R.A.M.C., whom I was asked to see because of severe abdominal pain. The history was that a week previously she had developed a sore throat. After this she began to complain of abdominal pain which was colicky in nature. In addition there was some backache. Between the attacks there was entire freedom from pain. As there was an appendicectomy scar the possibility of appendicitis was ruled out. All other investigations proved negative. The only conclusion I could arrive at was that this was a case of acute mesenteric adenitis. It is interesting to note that in this case the patient later developed acute rheumatic fever, which excluded her from being sent abroad.

These two cases, the one occurring in the course of scarlet fever and the other preceded by a sore throat and subsequently developing rheumatic fever, lend support to the theory suggested by Mr. Aird and others that acute mesenteric adenitis is due to a virus infection. In conclusion I should like to state that, although Mr. Aird has given us a complete description of this clinical entity, acute non-specific mesenteric lymphadenitis is a very dangerous diagnosis to make when confronted with an acute abdomen, especially in a child. One realizes how very variable the symptomatology of acute appendicitis is in children, and to withhold operation because of a diagnosis of acute mesenteric adenitis will, I feel sure, court disaster in many cases. For this reason I feel it is safer to look and see, rather than to be sorry afterwards.—I am, etc.,

London, W.1. Maurice Lee.

Sir,—The world of surgery should be indebted to Mr. Ian Aird for his very illuminating paper on non-specific mesenteric adenitis, for it is a condition that requires to be very much more widely known than it is at present.

I first became familiar with the condition about 18 years ago when acting as a full-time municipal surgeon. Children were frequently sent to me by local practitioners with a provisional diagnosis of appendicitis, in whom there was a history of *previous* attacks of abdominal pain, in many instances extending over a period of months or even years. I held the view, and I hold it now, that appendicitis in children is generally an acute fulminating disease leading on to rapid perforation and peritonitis; so much so that operation must be done forthwith. These cases with histories of previous attacks of abdominal pain, which rapidly resolved, leaving the child fit to return to school, did not fit in at all with my conception of appendicitis in children. The ones I operated on—and there were a fair number in those early days—almost invariably showed the distribution of swollen discrete mesenteric glands so clearly described by Mr. Aird, and like him I arrived at the conclusion that there was a definite syndrome in children, which I labelled loosely "mesenteric adenitis." I learned in time to differentiate those cases clinically and confidently abstained from operating.

I formed the opinion—perhaps without sufficient clinical proof—that the condition was largely due to the ingestion of unboiled milk, not so much the bovine bacilli as the numerous pathogenic organisms that result from the gross contamination of milk so prevalent in this country. When my own daughter, aged 6 years, who had never had one drop of unboiled milk up to that time, was operated upon for appendicitis I was impressed to learn from the operating surgeon that not one gland was pathologically enlarged. This finding naturally strengthened me in my belief. As regards accompanying factors I must admit that I found no constant association with upper respiratory infections, although I regarded this association as important in appendicitis, especially after learning that, in a girls' school, of 100 pupils with tonsillitis 25 required operation for appendicitis, and that in each case the same organism was found in the tonsils, the stools, and the appendix. Neither did I find an increase of cases at those times when upper respiratory infections were most prevalent.

However, the main point I wish to stress is the agreement with Mr. Aird that acute non-specific mesenteric adenitis is a definite clinical entity and, in spite of some obscurity about its cause, merits widespread recognition as an important disease, especially in children.—I am, etc.,

Wimbledon. N. L. Maxwell Reader.

Penicillin Pastilles

Sir,—Now that penicillin pastilles are coming into use, it is perhaps worth pointing out that if gelatin lozenges containing penicillin are allowed to dissolve *under* the tongue, in some people at least there appear demonstrable amounts of penicillin in the urine. These amounts are small in relation to the contents of the lozenges, and we presume that the blood level obtained by this method of administration is low. It would seem important, therefore, to remember that in the presence of an infection one may by this method contravene the generally accepted rule of chemotherapy that suboptimal dosage carries certain dangers.—We are, etc.,

A. C. Lendrum.
University of Glasgow. I. Lominski.

Spinal Analgesia in Operative Obstetrics

Sir,—Despite Dr. Louis Resnick's article (Nov. 24, p. 722), there are, I feel, a variety of objections to spinal analgesia in operative obstetrics.

First, there is a quite definite risk. Dr. Resnick presents a series of 393 apparently successful cases; but that does not eliminate the possibility—it is really a probability—of a fatality sooner or later from an "alarming drop in blood pressure." This drop is often met where spinal analgesia is employed in cases of abdominal distension, and is caused by the slow adjustment of vasomotor control after the removal of pressure. Whatever Dr. Resnick may say, the "risk" cannot be eliminated in obstetric cases, and spinal analgesia in such cases is, therefore, wholly unjustifiable.

The second objection concerns the suitability of the method. The majority of patients prefer to be asleep during operation. This seems especially desirable during manœuvres where a certain amount of force may be necessary, as in difficult forceps extractions. Accordingly, from the point of view of the patient's comfort general anaesthesia is the better choice, particularly as no obstetrician in my experience would agree to premedication with "omnopon 1/3 gr. and scopolamine 1/300 gr. . . . about 45 minutes before operation," as Dr. Resnick advises. At worst this may so depress the baby's respiratory centre as to result in stillbirth; at best there are anxious moments before the baby "gets going." In those cases for Caesarean section where a general anaesthetic is contraindicated, regional field block is a satisfactory and safe substitute, and, though admittedly the multiple injections are more unpleasant than the single one, the extra degree of safety obtained is the factor of paramount importance.

With regard to vaginal delivery, there is a very true dictum to the effect that if a patient is fit to undergo labour she is fit to have a general anaesthetic. Such anaesthesias are usually short, and the necessary manœuvres can be accomplished under gas and oxygen with minimal ether or trilene, or under cyclopropane O_2, according to indications.

Finally, apart from the question of fatalities under spinal analgesia, there are a number of possible unpleasant sequelae inherent in the method. The commonest, but by no means the most dangerous, of these is headache. Dr. Resnick admits its high incidence in his cases. It may be extremely intractable and is, of course, always annoying to the patient even if slight.

My own view is that in operative obstetrics spinal analgesia should be abandoned in favour of methods less fraught with potential danger and more suited to the conditions.—I am, etc.,

London, N.W.3. HELEN BOWER ALCOCK.

Sir,—It was interesting to read the recent article on spinal analgesia in operative obstetrics by Dr. Louis Resnick. While believing that the ordinary methods of inhalation and intravenous anaesthesia are indicated in routine work in operative obstetrics, I agree that spinal analgesia has certain advantages which make it the method of choice in certain types of case. The main indications are:

1. *Caesarean Section.*—In this operation the advantages of spinal analgesia are well known.

2. *"Failed Forceps" Cases.*—These patients have usually been given large doses of chloroform prior to admission.

3. *Destructive Operations on the Foetus and Difficult Forceps Deliveries.*—In this type of case the operative procedure is often time-consuming and apt to produce shock. Under spinal analgesia there is a surprising absence of shock and the general condition of the patient is much better than it would be under general anaesthesia. Furthermore, the operator has more time at his dispopsal and can go easily.

4. *Cases of severe toxaemia.*

It is a matter of common knowledge, however, that pregnant women are peculiarly susceptible to the effects of spinal analgesia when given by the ordinary methods. Some operators have experienced collapse due to a sudden fall in blood pressure directly upon the injection. Others have commented upon the high incidence of post-operative complications, particularly headache and retention of urine. Personally, I abandoned the use of heavy nupercaine some time ago on account of the high incidence of these post-operative complications. After this I evolved another method of giving nupercaine, based on Quarella's technique, and so far have obtained much better results apart from the absence of the post-operative complications mentioned I believe this method is safer.

The isotonic buffered spinal solution 1 in 200 is used. For cases requiring operative vaginal delivery the spinal needle is inserted between L 3 and 4 with the patient in the lateral position. A 10-c.cm. syringe containing 1 c.cm. of the nupercaine solution is attached to the needle and cerebrospinal fluid withdrawn to the 5-c.cm. mark. The syringe is now removed from the needle, the stylet quickly inserted to prevent loss of cerebrospinal fluid, and the contents of the syringe well mixed. The syringe is attached again to the needle and the solution injected very slowly at the rate of 1 c.cm. a minute. With this slow rate of injection a sudden fall in blood pressure is less likely to occur. For Caesarean section the spinal needle should be inserted between L 2 and 3, 1.5 c.cm. of nupercaine solution should be put in the syringe, and cerebrospinal fluid withdrawn to the 7.5-c.cm. mark. For operative vaginal delivery ephedrine hydrochloride 1 gr. is given intramuscularly. For Caesarean section it is not wise to rely on ephedrine for maintaining the blood pressure, and this drug should be omitted. Instead continuous intravenous adrenaline should be used as described by Evans (*Lancet*, 1944, **1**, 15). I regard this method of Evans as the most important recent advance in the technique of spinal analgesia.

I am glad to see that Dr. Resnick advocates premedication for Caesarean section. The ill effects of this have been exaggerated, and I am quite sure that the advantages far outweigh the disadvantages. Either heroin 1/12 gr., or omnopon 1/3 gr. with scopolamine 1/150 gr., can be given. I see no point in giving atropine to every case. It can always be given intravenously if spinal block should fail and general anaesthesia become necessary.

With the technique described above a 1 in 1,000 nupercaine solution comes *slowly* in contact with the nervous tissue, and as a result causes less physiological upset than in the heavy nupercaine technique, when a concentrated solution comes rapidly in contact with the nervous tissue. It is for this reason, I think, that there is less tendency for a fall in blood pressure to occur, and a much lower incidence of post-operative urinary retention and headache, with the method described.—I am, etc.,

Stockport. JAMES ROSS.

Sir,—Dr. Louis Resnick has made such a good case for spinal analgesia in his very able article that there would appear to be some danger of its routine adoption for operative obstetrics by others with less experience of the technique or appreciation of the risks. It would seem prudent to utter a word of warning.

So far from holding an unreasonable prejudice against spinal analgesia, I appealed for an eclectic attitude towards its use (*Journal*, March 7, 1942, p. 339), and would now urge that this also be applied to its use in connexion with Caesarean section and operative vaginal delivery. Every new drug or agent for the production of anaesthesia or analgesia—general, local, regional, or spinal—is tried in obstetrics; some are discarded, others retain a limited sphere of usefulness; none has proved universally applicable; so let it be with heavy nupercaine.

Caesarean section presents certain marked points of difference from any other abdominal operation:

1. *Psychological.*—There is inevitably more tenseness, more drama. To the normal pre-operative apprehension on the part of the patient are added the hopes and fears of the mother for her unborn child; nor can these be dulled by heavy premedication, most surgeons insisting on a minimal amount or even none. Should the baby be apnoeic the routine of respiratory resuscitation, however quiet and well ordered, or the hiss of escaping oxygen is no substitute to the conscious mother for a lusty cry.

2. *Technical.*—The rapid removal of a large abdominal tumour coinciding with a sudden loss of blood do not go well together with the change in haemodynamics associated with normal spinal analgesia. The laxity of the abdominal wall ensures ease of closure.

The percentage of spinal headaches seems a high price to pay for relaxation so easily obtained by any competent anaesthetist who has cyclopropane, gas-and-oxygen with minimal ether or trilene, pentothal alone or in combination, from which to choose; and with any of these can provide ideal operating conditions with safety to mother and child with negligible or no unpleasant sequelae.

Operative Vaginal Delivery.—The well-known effect of a spinal in inhibiting the action of the longitudinal muscle fibres while increasing that of the circular fibres, thus producing a violently contracting uterus with poor expulsive power, should be a sufficient contraindication without suggesting the undesirability of performing destructive operations such as perforation and craniotomy in the conscious patient.

Since the risks of sepsis would be greatly increased in domiciliary midwifery, the doubtful advantage of being able to combine the functions of anaesthetist and accoucheur is further vitiated, since only in extreme emergencies is it justifiable for one person to administer an anaesthetic and operate; such circumstances should be rare in hospital practice.

Finally I should like to submit the following indications for spinal analgesia in obstetrics: (1) the presence of metabolic or respiratory disease of such a degree as to render the skilful employment of a general anaesthetic a greater risk than a spinal; (2) the absence of an anaesthetist capable of producing satisfactory operating conditions with safety to the patient by means of general anaesthesia.—I am, etc.,

Aylesbury. H. W. LOFTUS DALE.

Acute Inversion of the Uterus

Sir,—It may be of interest to record another case of inversion of the uterus treated by the method described by Mr. J. V. O'Sullivan (Sept. 1, p. 282). This patient, a primigravida of 23, was admitted to St. Luke's Hospital, Bradford, on Nov. 10, profoundly shocked. The history is as follows:

L.M.P.—Jan. 18; E.D.D.—Oct. 25. In the antenatal period there were severe headaches and oedema.

Nov 9, 1945.—12.00 hrs.:—Labour commenced.

Nov. 10.—13.00 hrs.: Normal delivery of full-term child; 9 lb 1 oz 14.30 hrs.: Placenta and membranes expressed. Patient suddenly collapsed, pulseless; total loss 1 pint. The resuscitation van was called and plasma drip started, three pints being given. B.P. could not be recorded. 17.30 hrs.:—Admitted to hospital; pulse not palpable, B.P. 70/50; indefinite swelling in lower abdomen, very little loss. 18.30 hrs.:—Blood transfusion, 1 pint. Pituitrin m. 4, ergometrine 0.5 mg.; no improvement followed. 19.30 hrs.:—Ten ounces of urine withdrawn; the abdominal swelling was now no longer palpable. Per vaginam a large, firm, shaggy mass could be felt protruding through the cervical rim; it was tender to touch. Two or three pints of dettol lotion at 120° F. were run into the vagina while the introitus was blocked by hand. This was but imperfectly accomplished because of the size of the operator's hand. The manœuvre was only partially successful, although the uterus, with a depression at the fundus, could now be palpated abdominally. A second pint of blood was now given.

I saw the patient at 20.45 hrs., when she was profoundly shocked, B.P. not registering. The shock was greatly exaggerated by the simplest vaginal manipulation. About 6 pints of dettol lotion were run into the vagina, better occlusion being obtained by my larger hand. The fundus rose steadily, and eventually no depression could be palpated abdominally. The douche was then discontinued. Ergometrine 0.5 mg. was injected into the drip-tube. At the conclusion of this operation the pulse was still not palpable and the B.P. could not be registered. 22.00 hrs.:—Pulse still impalpable, B.P. 65/40, fundus rather soft, no vaginal bleeding. Third pint of blood given. 23.00 hrs.:—Fourth pint of blood given.

Nov. 11.—00.45 hrs.:—B.P. 105/60, condition much improved. 09.30 hrs.:—B.P. 120/70, pulse 100, condition good.

Subsequent Progress.—Rise of temperature on the third day, fundus not tender. Involution proceeding satisfactorily, lochia normal. Local cellulitis around the site of the intravenous wound.

The points which seem to me to call for comment are: (1) The profound shock with small loss of blood, aggravated by the slightest vaginal manipulation and failing to respond to antishock treatment. (2) The absence, in this case, of a *dramatic* recovery from shock—in contradistinction to the case recorded by Dr. Daley. It will be observed that a period of two hours followed the reposition of the partial inversion before the blood pressure returned to 105/60. (3) The simplicity of the treatment.—I am, etc.,

Bradford. E. GLEDHILL, M.R.C.O.G.

Acute Yellow Atrophy after Trilene Anaesthesia

SIR,—Major K. N. A. Herdman's description of a case of acute yellow necrosis of the liver following trilene anaesthesia (Nov. 17, p. 689) prompts me to recall a case of my own experience of acute yellow atrophy as a late sequela of burns, which I saw some 18 months ago. My case, though similar in many respects to that described by Major Herdman, differs from it by the fundamental fact that at no time was trichlorethylene administered to the patient. Yet acute yellow atrophy supervened. I do not recall all the details of my case, but the history is briefly as follows:

A soldier aged between 30 and 25 years, in good health hitherto and without serious illnesses in his past history, was admitted to hospital suffering from second-degree burns of face, arms, and chest. He was moderately shocked, and antishock measures were instituted at once. Surgical toilet was carried out approximately two hours after admission, under pentothal (0.5 g.), nitrous oxide and oxygen. The patient was very ill for a few days, but then made a slow but steady recovery. Sepsis was slight. No further anaesthetics were administered. Some six to seven weeks later, when he was almost due to be discharged, he suddenly developed jaundice, which rapidly became deeper; vomiting set in, and despite prompt treatment the patient died in coma a few days later. Necropsy revealed acute yellow atrophy of the liver.

In comparing this case with the one published by Major Herdman, what, then, are the factors, if any, common to both? Both patients received a small amount of pentothal, but, while symptoms in Major Herdman's case appeared a few days after its administration, jaundice in the second case set in more than six weeks after anaesthesia. Moreover, it has now been established that pentothal has no deleterious effect on the healthy liver, being broken down in the blood stream itself. And in my case, at least, not sufficient time had elapsed between the accident of burning and the administration of pentothal to conceive the possibility of gross liver damage, due to the burns, at the time the pentothal was given. Thus to my mind pentothal can be excluded as the culprit. The only common factor in the two cases then are the burns themselves, followed after several weeks by symptoms of hepatic damage.

In the absence of any other known cases of yellow atrophy due to trilene, is it not safe to assume that the condition might be due to the deleterious effect of some abnormal metabolites, toxic to the liver parenchyma after absorption from the burned areas, causing severe symptoms only after some weeks have elapsed?—I am, etc.,

G. M. WYANT,
Ashton-under-Lyne. Capt., R.A.M.C.; Graded Anaesthetist

SIR,—One cannot help feeling alarmed at Major K. N. A. Herdman's account of yellow necrosis of the liver following trilene anaesthesia. Ever since Dr. Langton Hewer's reports to the Royal Society of Medicine in May and July, 1943, I have used the agent—fortunately never with a closed circuit, as I had never seen it so used—as an adjuvant to nitrous oxide and oxygen, and one is tempted to inquire, "Was all that trilene really necessary?" Two ounces seems a large quantity when unconsciousness and immobility are all that are required and the patient has been very adequately premedicated with morphine 1/4 gr. and hyoscine 1/100 gr. followed by 0.8 g. of pentothal. If his liver was damaged already surely he would not have required 0.8 g. pentothal to produce unconsciousness, so the chances are that he had more than a "sleep dose" of pentothal. Surely before any long operation the patient should always have glucose, and some of the more efficient ward-sisters administer it pre-operatively by mouth without being asked.

As I have found it possible to maintain anaesthesia for long operations (anything up to six hours) with only a few drachms of trilene without complaint from the surgeon, I am wondering whether, since the reflexes were brisk when the patient left the table, he was unusually anaesthetic-resistant but with an impaired liver, or whether he could have been "kept under" with less trilene.—I am, etc.,

London, S.W.13. MARGARET JOAD.

SIR,—Major K. N. A. Herdman (Nov. 17, p. 689) reports a case in which the patient died of liver necrosis some eleven days after a general anaesthetic which included, among other agents, the administration of 2 oz. of trilene. He suggests a parallel between this case and delayed chloroform poisoning, but emphasizes that such a complication of trilene anaesthesia has not hitherto been recorded. Burns, sepsis, and malnutrition are considered and rejected as possible factors producing liver damage in this case. The necropsy report lacks detail, but the liver necrosis would appear to be as much in keeping with an infective as a toxic hepatitis, and it seems to me that epidemic infective hepatitis or homologous serum jaundice should be kept in mind. It would be interesting to know more about the treatment of this case between March 4 and April 14 with reference to plasma transfusion and the use of pentothal anaesthesia. Injection of an icterogenic agent between these dates and the onset of symptoms of hepatitis on June 5 gives an incubation period compatible with that of homologous serum jaundice (93 to 52 days). Epidemic infective hepatitis is probably less likely, as this would assume infection of the patient while in hospital, although it is known that infective hepatitis was not uncommon in the B.L.A.—I am, etc.,

London, S.W.13. S. M. LAIRD.

Acroparaesthesia

SIR,—We are indebted to Dr. F. M. R. Walshe for his re-description of acroparaesthesia (Nov. 3, p. 596). He renders the concept unmistakable, and so stimulates further investigation. May I be permitted to submit some points of difference and amplification regarding this syndrome.

(a) Though commoner by far in women, it is not confined to females.

(b) It is not confined to persons greatly physically fatigued or even with muscular atony.

(c) Dr. Walshe's implication that it is not always associated with observable clavicular sagging is confirmed. (He records his impression that such sagging is "commonly" seen in these cases.)

(d) It may undergo remission without physical environmental change. Physical rest is not always indispensable in therapy.

(e) A very comparable state can occur in the feet, though, for fairly obvious reasons, patients do not complain of it so much in this site, and I have not met it rivalling manual disability in extent.

(f) A further objective sign occasionally occurs, in that the finger-tips look as if pinched side to side. Viewed from below the comparative semicircle is replaced by a decided peak. This pinching will modify slowly if there be long-period fluctuations in the acroparaesthesia. As a permanent state the variant is not pathognomonic of this syndrome.

Some queries would appear to be relevant.

(1) Is not rest for a harassed housewife likely to affect a great deal more than her thoraco-clavicular relations? (I cannot follow Dr. Walshe to his "logical conclusion" that, since "a rest or holiday affords remarkable relief," "it suggests a mechanical origin for the syndrome.")

(2) If a "great majority" of cases are indeed due to these mechanical factors, what are the other cases due to? (I agree with Dr. Walshe that "the temptation to find a single pathology for a well-defined syndrome is a strong one, and may often be fallacious." When a human being is in dis-ease, pathology is never "single" in the sense in which he presumably used that word. Traction on, or compression of, the brachial plexus may well play its part in some persons. I have no intention of suggesting that any other factor may singly be operative. Are there not exactly as many pathologies as there are patients?)

(3) Has Dr. Walshe tried the effect of having a colleague of his treat control cases by the regime of comfort and massage he prescribes, but with down-traction applied to the clavicles?

(4) How is it that germinal fringes of the syndrome (uselessness and tingling of the hands for a fleeting period after awaking) commonly occur in people who do not often, for this complaint, come to the neurologist or indeed to any doctor practising medicine?

(5) Dr. Walshe has propounded a term novel to most of us—"medicine proper." It is not clear what he includes under this new term; could he be more explicit?

In the past month I have met typical bilateral manual acroparaesthesia in a young R.A.F. officer of powerful physique, whose cervico-thoracic area showed no *x*-ray abnormality and who had been doing no heavy manual work. He passed through an emotional disturbance of considerable magnitude, after a certain phase of which his acroparaesthesia disappeared. Nor was there (to use Dr. Walshe's own words) sacrifice of any dietary, vitamin, or physiotherapeutic "goat to Aesculapius."—I am, etc.,

Major, R.A.M.C.

Artificial Pneumothorax Refill

SIR,—I was interested to read Dr. Alastair Allan's description of an improved artificial pneumothorax needle (Nov. 3, p. 607). It certainly has the advantage of permitting the continuous reading of the intrapleural pressure while the refill is going on; this will minimize the danger of introducing air into a pleural or pulmonary vessel. But it has been shown that air embolism occurs most frequently at the initial plunge of the A.P. needle, before the operator has the opportunity of reading the manometer or introducing air.

The points in favour of Dr. Allan's needle are counterbalanced by two shortcomings: first, the large diameter, which necessitates the use of local anaesthetic in all cases of refill; secondly, the two separate air channels, thus increasing greatly the chances of accidental blockage of the needle during its passage through skin and parietal pleura. Writing about the usual type of A.P. needle Dr. Allan remarks: "During the refill—the dangerous period—no reading can be observed." But this surely can be successfully remedied by switching off the air as frequently as needed and taking manometric readings.

I agree with Dr. C. F. Hawkins (Nov. 24, p. 742) that the use of an ordinary A.P. refill needle is practically painless. Needless to say, the point of the needle has to be sharp and the needle inserted by a quick plunge. Mayer (Packard *et al.*, *Artificial Pneumothorax*, 1940, p. 73), describing the technique of refills, states that "many workers do not employ a local anaesthetic for refills because the operation is usually painless." The reason why so many patients ask for local anaesthetic is that they remember the sometimes lengthy and laborious procedure of A.P. induction, and do not realize the difference between the latter and the subsequent refills. Several patients I persuaded to try a refill without "local" expressed afterwards the wish to continue without it. Many others spontaneously ask to discontinue the use of local anaesthetization, saying that they do not mind the "needle prick." The local anaesthetic seems to have primarily a psychological effect; patients who have never had local anaesthesia do not ask for it.

From a fairly large experience of collapse therapy in Paris hospitals I concluded that a local anaesthetic is unnecessary and anyway is unknown there. I may quote here the authority of the late Dr. Michel Léon-Kindberg, eminent French phthisiologist, under whom I had the privilege to work in Paris None of his patients, whether in- or out-patients, ever received preliminary local anaesthesia before A.P. refill. I can remember no instance of air embolism or shock. Air embolism probably may occur whether the needle track has been anaesthetized or not. The pathogenesis of pleural shock is as yet completely obscure, and must be very rare in cases of well-established A.P. How much novocain or procaine will avert the occurrence of pleural shock is also unknown. Yet we know that certain individuals are hypersensitive to cocaine derivatives used locally. Thus Packard (loc. cit., p. 92), discussing what he terms the symptom-complex of pleural shock and gas embolism, draws attention to the importance of derivatives of cocaine in causing acute toxic manifestations indistinguishable from those of pleural reflex or air embolism. Some other workers find also that reactions and pleural effusions are less often encountered if no anaesthetic is used.—I am, etc.,

St. Charles' Hospital, London, W.10.

A. I. SUCHECKI.

SIR,—Dr. C. F. Hawkins disagrees with Dr. A. Allan's quotation about the use of local anaesthetic in pneumothorax refills. May I range myself on the side of Dr. Hawkins. It has been my experience that once a patient has been refilled without the use of an anaesthetic it is almost invariably the method of choice for that patient thereafter. I have on several occasions during the past year conducted a census of opinion among my own patients. Out of a total of approximately 200 individuals only three have stated a preference for an anaesthetic, and two of them became ultimately converted. The third is a rather excitable female patient who prefers not to take a chance.

I find that the insertion of the needle is greatly facilitated by a simple manœuvre. This consists of placing an ordinary hard pillow folded lengthwise and tied with a bandage under the patient's waist. The patient lies on the unaffected side, and is rolled partly towards the operator. The arm is extended above the head. This not only increases the available space between the ribs but stretches the intercostal structures and makes it extremely easy to insert the needle and actually to feel its passage through the parietal pleura.

In answer to those who stated that the giving of a local anaesthetic makes it possible to confirm the presence of a free pleural space, I would point out that there is no guarantee that the A.P. needle will be inserted exactly the same distance or in exactly the same place as was the needle through which the anaesthetic was administered. In any case, the presence or absence of a space should have been ascertained by previous screening.

Perhaps the whole argument is summed up in the words of my patient who, when offered the choice, said: "It depends on who is doing it, Doctor."—I am, etc.,

Noranside Sanatorium, Fern, Forfar.

PHILIP H. DALGLEISH.

SIR,—I endorse the remarks of Dr. C. F. Hawkins (Nov. 24, p. 742) against Dr. Alastair Allan's quotation that "humanity and common sense call for anaesthetization of the needle track." I find that, with an experience of close on 2,000 refills annually, patients from all walks of life invariably prefer the operation without a local anaesthetic; indeed all my patients refuse such. Immediately before refill the extent of the pleural space should be observed by screen or film examination, noting particularly the position of the lung border at the end of both inspiration and expiration. If two radiographs are taken, one at the end of both phases, they will show in sharp contrast the different positions of the collapsed lung border, the second showing the obviously greater distance of the lung-edge from the chest wall; and, incidentally, the presence and site of adhesions will be seen to greater advantage in the second.

The needle should accordingly be inserted during the natural pause which takes place at *the end of expiration*, thus obviating any risk of injury to the lung, which at this phase is *more out of reach*. There should be no sudden stab. The patient should be instructed to inspire, then expire, and then stop breathing. A Morland needle with a very sharp spear-headed point is next placed *on* the skin in the appropriate interspace and then, comparatively slowly and deliberately, pushed through skin and pleura. The following inspiration on the part of the patient will then show the maximum inspiratory swing on the manometer, the clip on which should be left open and air allowed to enter the pleural cavity at low pressure, thus avoiding air embolism, undue pull on any adhesions, and possibly subsequent pleural effusion.

Incidentally, it is worthy of note that after induction a puddle of fluid immediately collects at the bottom of the pleural space. This is not to be confused with the onset of pleural effusion; it is simply due to the new position taken up by the lymph, which, before induction, normally bathed the pleural surfaces, including the interlobes. This phenomenon can be observed on the *x*-ray screen or radiograph if the patient is examined immediately after induction, provided the mechanical diaphragm on the *x*-ray plant is sufficiently widely open to include the lowest depth of the costo-phrenic sinus.—I am, etc.,

Cambridge. W. Paton Philip.

Sir,—I read the correspondence on the humane A.P. refill with much interest. I entirely agree with the views expressed by Dr. C. F. Hawkins. I gave up the use of local anaesthetic after careful investigation of a considerable number of A.P. cases. A random sample of A.P. cases were selected at each refill session; one would be given a local anaesthetic and another no local. When this had been done over a period each patient at different times had a refill with and without anaesthetic. Only two patients expressed a desire to have a local anaesthetic before refills; the others preferred refills without a local anaesthetic. It is interesting to note that the two patients who preferred to have local anaesthetic before refills were given refills after sterile-water injections and declared that the refills were less painful than without a local anaesthetic. Owing to the prolonged nature of the treatment it is decidedly beneficial to the patient not to have injections of either cocaine or novocain before each refill; but if the patient expresses a desire to have a local anaesthetic I give it.

I do not believe that the danger of pleural shock in an established A.P. is greater when local analgesia is omitted. I have had only one case of pleural shock in an established A.P. case in a series of over 15,000 refills, and this occurred in a transfer with a history of several so-called fainting attacks after refills and to which no reference was made in the case notes on transfer. It is interesting to note that the same patient developed pleural shock following the development of pleural friction on re-expansion of the lung. I regard this as redux pleural shock. —I am, etc.,

H. P. Fernandes,
Derbyshire Sanatorium, Chesterfield. Medical Superintendent.

Latent Disease in Far East P.O.W.s

Sir,—The prisoners of war from the Far East are nearly all home by now and about to be demobilized. Many of them are suffering from diseases which may give them trouble in after-life. Stool examinations done on them by Sergt. Baptist, S.S.V.F., as prisoner of war, and later in Rangoon under the aegis of Lieut.-Col. G. A. Ransome, I.A.M.C., showed that about 40% had some intestinal parasite, 13% *Entamoeba histolytica*, 30% ankylostomiasis (by saline concentration), and a few cases of trichomonas and *Strongyloides stercoralis*. Examinations carried out on the troopship coming home showed 3% with enlarged livers. *Entamoeba histolytica* cysts were found in the stools of a high proportion of these. Anaemia due to hookworm is rather more rare, but is present in an appreciable number. Deficiency neuroretinitis leading to reduced vision with central scotoma is particularly common among those who did not leave Singapore Island. Chronic malaria seems to have responded in most cases to the six-weeks prophylactic mepacrine course. Old tropical ulcer scars may become eczematized and break down. (The figures quoted here are rough computations and should not be taken too seriously.) Psychoneurotic manifestations are seen chiefly among the civilian internees, who had more attention from the Japanese Gestapo and worse food than the military.

I very much doubt whether the routine demobilization medical examination includes a microscopical stool examination, so it is probable that some of these cases will be coming into the hands of civilian doctors, especially in East Anglia, the soldier having been demobilized without the condition having been spotted while still in the Army. It is up to the medical practitioner to see that these men have a square deal as regards financial compensation for lost hours of work and pension.—I am, etc.,

Ealing, W.5. F. E. de W. Cayley.

The Saline Infusion Bottle

Sir,—Since the blood transfusion services unanimously adopted the Medical Research Council's transfusion bottle for the supply of blood, plasma, and serum many hospitals have been led to use it for all intravenous solutions. In most large hospitals the various saline and dextrose saline solutions used for intravenous infusion are made up by the pharmacist and delivered sterile in M.R.C. bottles.

These bottles, however, are too small for the average routine saline infusion. Unlike blood, saline is commonly required in quantities of 10 or even 20 pints (over the course of several days), and the frequent changing of the one-pint bottle is inconvenient, especially at night. Moreover the washing, filling, sterilizing, and labelling of multiple small bottles give the pharmacist unnecessary work. It is perhaps not sufficiently realized that the expense of a saline infusion lies mainly in the handling of the bottles; the larger the bottles, the cheaper is the infusion. Even in sterilizing, where one would suppose that the autoclave would take only a certain volume of saline irrespective of its containers, the big bottle is still economical, for an autoclave with a capacity of 16 pint bottles will often take 10 of quart size. Anyone doubting these facts should examine the prices of the commercial article; the pint and the quart cost almost the same.

If the quart is the best size for saline, why is it not in general use? Unfortunately those patterns at present available differ from the standard in all their dimensions, so that their use entails the provision of two types of "giving set." This is the crucial point. To avoid it we require a companion to the standard blood bottle with the same size of mouth and same height, and a double capacity accommodated laterally. It seems that no such bottle is made. We have approached the United Glass Bottle Company (makers of the M.R.C. pattern), but they can offer nothing suitable from stock, and to begin manufacture would require an order for a larger number than any single hospital could use.

United effort is required. We find that the Medical Research Council is handing over its wartime responsibility in this field. We have heard, with some alarm, that this subject has been discussed recently among those who are particularly concerned with the organization of the blood transfusion services, and that there was such diversity of opinion that no decision could be reached. Perhaps some of the points of disagreement will appear in subsequent correspondence. For our own purposes we are in no doubt as to the type of bottle we require. We would place an order for it if, through the kindly medium of your *Journal*, we could find a few hospitals who would join us.—We are, etc.,

J. C. H. Hanson, Pharmacist.
Hertford County Hospital. T. C. Beard, R.M.O.

Subcutaneous Oxygen for Sciatica

Sir,—In your correspondence columns (Nov. 17, p. 703) Dr. H. Avery writes on the treatment of sciatica by subcutaneous injection of oxygen, and refers to a letter of mine (Oct. 20, p. 544). He used for the purpose an oxygen injector with bag reservoir supplied by the Sparklet Company. He "used this treatment when all others had failed . . . and had a large number of spectacular cures, until on one occasion (the needle having apparently slipped) my patient suddenly complained of pain over the heart and faintness; in fact he presented a complete picture of air embolism." Fortunately the treatment was successful. The patient rapidly improved and walked home half an hour later. He has never had any sciatic pain since, neither has Dr. Avery used the treatment again.

There was an excellent account of the methods of diagnosis and treatment of sciatica given in vol. 3 of *Modern Technique in Treatment* (published by the *Lancet* in 1927), written by Dr. J. P. Martin when assistant physician to the National Hospital, Queen Square. He defines sciatica as an inflammation of the interstitial tissue of the sciatic nerve or its roots. This is the true neuritis, and a correct diagnosis is essential.

Dr. Martin described the method of injecting oxygen into the subcutaneous tissue over the nerve from a cylinder via a washbottle with warm water until the surrounding tissues are thoroughly distended and ballooned. "These injections often give the most surprising relief" and the "extreme simplicity [of the method] makes it always worth trying."

The oxygen treatment was also recommended by Dr. James Collier, who was physician to the Queen Square Hospital, and described by him in Price's *Textbook of Medicine*, 3rd edition, page 1656, as "a simple and harmless process which is quite painless and often brings most surprising relief." I can thoroughly endorse these opinions from my own experience with cases of sciatica when all other methods had failed (*vide British Medical Journal*, Feb. 12, 1944, p. 230).—I am, etc.,

Worthing HERBERT H. BROWN.

The Child with Frequent Colds

SIR,—The article by Drs. Irwin and Frankel (Oct. 27, p. 566) has already attracted attention from several contributors, who have offered appraisals and criticisms. One factor which seems to have escaped all mention so far concerns the influence of a properly balanced diet on the problem of susceptibility to disease in general and to catarrhal infections in particular. No attempt was made to investigate in detail the dietetic habits of the 130 children under review or to classify them into acid and lymphatic or alkaline groups. For instance, the importance of the acid-producing foods, as chiefly represented by bread, sugar, and meat, if consumed in too great a proportion, is well recognized as a cause of diminished tissue resistance. Since it is true that the children of the poorer classes live mainly on acid bread and are the first to fall victims to epidemics, it is a fair assumption that the children of the not-so-poor frequently fall short of the properly balanced diet due to the lack of sufficient basic or alkaline foods, such as vegetables (raw and cooked), fruit, milk and its products. Many physicians recognize the "catarrhal" type of child, with its exaggerated "mucoid" reaction, especially in regard to the nose and throat, and the remarkable improvement which can be effected by reducing to a minimum such unsuitable carbohydrates as refined sugar and white bread and adjusting the balance as circumstances permit. This may sound an over-simplification when one realizes that even the correct foods must have the qualities of freshness and vitality that are hardly ever to be found in tins and never in large cities. Nevertheless the principle holds good, and I believe that, had the authors attempted to include in their investigation an evaluation of the dietetic habits of the children on the above lines, it is almost certain that their conclusions would have yielded something much more valuable than the negative results recorded.—I am, etc.,

Kilmacthomas, Co. Waterford. P. G. DOOLEY.

SIR,—My observations lead me to believe that it is children who have been subject to the process of "spoiling" and are in consequence neurotic who suffer most frequently from common colds. These occur despite, or most likely because of, the physical care lavished upon them. Spoiling consists of a mixture of savage restriction of the child's activities on the one hand and lavish indulgence on the other. As a consequence the child is constantly in that emotional state which is the primary cause of the common cold, or perhaps I had better say is the predisposing cause of it. I am sure it is a most dangerous procedure to act—especially surgically—on the assumption that colds have invariably a physical causation. Indeed, such an assumption is contradicted by many facts open to observation.—I am, etc.,

Leeds. E. WRIGLEY BRAITHWAITE.

Significance of the E.S.R.

SIR,—Recent correspondence on this subject emphasizes once more the wide divergence of opinion regarding its value. True, we still do not know what the E.S.R. is measuring, but, whatever the essential mechanism by which the stability of the blood is upset, the interpretation of the result in terms of tissue destruction gives valuable information to the clinician. Determination of the E.S.R. gives a measure of a state or condition, just as determination of the body temperature gives a measure of the febrile state. The one test does not claim to be any more specific than the other. The position has been further obscured by over-elaboration and differences in the methods employed. One would expect widely different results between the original Westergren method, using blood diluted 1 : 4 with 3.8% sodium citrate, and undiluted blood prevented from coagulating by the addition of dry potassium oxalate, even when set up in similar tubes; but so long as one method is used the results are comparable.

The lack of uniform standard values even with the same methods, and of agreement as to the extent of physiological variations, undoubtedly invites criticism and further research. In spite of these drawbacks, however, there are many clinicians who are satisfied that it is possible to get useful information from this test, when it is used, as any experimental procedure ought to be used, as one link in the chain of evidence on which a diagnosis or an assessment of progress may be founded. Too many of its detractors expect the E.S.R. to give information which it is incapable of giving, whilst refusing to accept the information which it can give.

May I cite one example of a situation in which the E.S.R. gives information not provided by any other procedure. The diagnosis of acute endocarditis is often a matter of great difficulty (Price's *Textbook of Medicine*, 1937), since it is not infrequent to find a mitral systolic murmur due to anaemia or simple dilatation. With a true endocarditis the E.S.R. is markedly accelerated, far beyond even the most optimistic of physiological limits, and it should be noted that this information is available in the early stages, just when it is most valuable. Indeed, it is frequently present before there are any localizing signs. Again, it is very difficult to decide whether the lesion is still active after convalescence is apparently established. The E.S.R. gives accurate information on this point, particularly if the result is graphed by 15-minute readings over the hour. My attention was first directed to the value of the E.S.R. in this type of case by the article by Oakley (*St. Bart's Hosp. Rep.*, 1936, 69, 241), and my own experience in dealing with endocarditis in scarlet fever would lead me to support the views expressed by Dr. J. W. Shackle (Nov. 24, p. 742) rather than those of Drs. D. G. McIntosh and D. M. Keay (Oct. 27, p. 584).—I am, etc.,

JAMES KELMAN.

Diet in Morphine Addiction

SIR,—In reply to Dr. Clifford Allen's letter (Nov. 17, p. 705) I must confess that I have never had the opportunity of treating a morphine addict suffering from pellagra. My assertion that "in no circumstances have I ever known a patient to gain weight in the first two weeks of treatment" referred to addicts only, and not to addicts suffering from pellagra.

I do not question that cases of pellagra respond rapidly to treatment and gain weight within a few days, but it certainly surprised me to read about a morphine addict, of twelve years' standing, with pellagra gaining weight within eleven days in spite of the fact that morphine was entirely withheld. I have no quarrel whatsoever with the treatment given, and, far from offering any criticism, indicated that intensive vitamin therapy, which I have employed with gratifying results in the treatment of drug addiction, might have been responsible for the "cure" in the case described by Comerford and Kirman (July 14, p. 44). My communication (Oct. 20, p. 547) nevertheless did intentionally convey considerable doubt regarding the "cure," not of the pellagra but certainly of the drug addiction.

Many authorities assert in the most unequivocal terms that there is no such thing as a cure for narcotic drug addiction. Dr. Allen's statement that he cannot believe that the patient could obtain a supply of morphine over a period of several months while under mental hospital observation is so naive that it prompts me to inquire how many cases of drug addiction he has endeavoured to manage. The fact that the patient "could walk several miles after discharge" is just as consistent with the persistence or relapse of the addiction as it is with cure.

The point of my letter was certainly not unfairly to criticize an account of an interesting case, but to suggest that a not inconsiderable item in the symptom-complex of drug addiction is a dietetic and vitamin deficiency.—I am, etc.,

London, W.1. ELLIS STUNGO, Major, R.A.M.C.

Avitaminosis and Arcus Senilis

SIR,—Having seen in one week a so-called arcus senilis in two men of 25 and 28, both of whom had suffered from beri-beri while in the hands of the Japs, I wonder whether avitaminosis may not have been the cause, as a case of an incomplete arcus seen a year ago in a middle-aged patient has cleared up entirely under better living conditions. A tendency to early arci may be familial, though the earliest age at which I have seen it was in a colleague in the last war; he was 24 and had an almost complete circle in both eyes.—I am, etc.,

London, W.1. SYDNEY TIBBLES.

Politics and Medicine

SIR,—There is much latent criticism of the profession's policy of "Wait and See" towards the new Health Services Bill. It seems to me that it might be useful if some fundamental principles were brought forward in the columns of the *Journal*. To start the ball rolling, I suggest that the profession should agree that politics should play no part in the advancement of doctors in their profession. A parallel case is discussed by Marshal Foch in the preface to his Memoirs. He points out that Joffre, before the war of 1914–18, "had made it possible to reduce, but not entirely eliminate, the number of inefficient general officers whose political opinions had won them their commands. . . . It may be remarked in passing that the very position of an officer should prohibit him, whether in time of peace or of war, from mixing up in the struggles and quarrels of politics." This is arguable, but Church of England clergymen and civil servants are not allowed to sit in the Commons. Foch then goes on, "His professional value can reveal itself only on the field of action before men of the same trade, his peers or his superiors; it cannot be estimated by political men. . . . Politics bring to the choice of Army officers nothing but error and injustice, two causes which more than anything else tend to enfeeble that body of public servants." It would be a great mistake if key positions in the new Health Service were given to medical men because of their political opinions. And if once appointed they can be got rid of only with the greatest difficulty, as Joffre found when he tried to unstick Sarrail.—I am, etc.,

London, W.1. WILFRED SHAW.

The Aim of Medicine

SIR,—The aim of modern medicine should be the "good life" as the Greeks understood the term. The fit body and the fit mind must go together, and to achieve this we should aim at complete mental, physical, and emotional development. Unless we do this various phases of our personality are in different stages of development, and they will cause emotional instability and conflict within the personality and also with the outside environment.

As Dr. Harry Coke says in his letter (Nov. 10, p. 667) there are many physiological responses to emotional stimuli, probably associated with a pituitary dysfunction. But surely to treat merely the dysfunction of the pituitary is to treat only the symptoms of the disease and to leave the cause itself undiscovered and untreated. Similarly in the treatment of a peptic ulcer the underlying cause should also be treated, otherwise the ulcer is apt to return. Also such metabolic disorders as atheroma and arteriosclerosis starting early in life, and essential hypertension, probably have a background of nervous stress and emotional frustration.

As any doctor who has worked in general practice knows, there is a close association between the antisocial or frustrated and the person suffering from subnormal health. These people already form a large proportion of any medical practice, and as more organic diseases are controlled they will form an increasing percentage. There is a solid mass of chronic ill-health among people leading unsatisfactory lives in rooms, hotels, and boarding-houses which will never be cured by orthodox methods.

I had an extreme case of social maladjustment and chronic ill-health some time ago. A man of 47, physically fit, came to me complaining of psychological impotence. He was an intelligent man of some charm and culture, had always been, but became a heavy drinker and gambler. He lived apart from his wife and had had at least three illegitimate children for whom he had been astute enough to evade responsibility. His early history was as follows: He was orphaned at an early age and joined a cavalry regiment in the 1914–18 war. When his regiment was turned over to infantry he decided this would be too hard work for him. Unfortunately he was able to regurgitate and vomit at will, and he immediately decided to put this faculty to some practical use. He was admitted to hospital and literally vomited his way through nine different hospitals, and after eighteen months in hospital, having lost 3 st. in weight, he was discharged from the Army. He then carefully fed himself up and joined the Royal Flying Corps. Since I treated him in 1943 this man has had a nervous breakdown, and his impotence has been sufficiently cured for the girl friend of the moment to have become pregnant.

How many men have been invalided from the Services in two wars as being psychologically unsuitable, with their neurotic and antisocial traits still untreated, to lead a life of ill-health or perversion causing trouble wherever they go? We as doctors realize that emotional maturity is as essential as physical maturity for adult well-being, and until we are given facilities to treat these cases effectively there will be a great mass of subhealthy and mentally abnormal people in the country.—I am, etc.,

Chepstow. MARY R. ANDERSON.

Training for Released Service Doctors

SIR,—I am glad to see that Col. C. D. Evans (Oct. 27, p. 585) has drawn attention to the unhelpful Government policy in regard to the further training of doctors who were starting to specialize before being called up. My own experience has shown that this policy, which looks so good on paper, will provide but little assistance to many returning medical officers who would now, but for the war, be well on their way to becoming competent specialists.

I joined the R.A.F.V.R. medical branch in 1937 on qualifying, and had intended to take the F.R.C.S. and M.R.C.O.G. with a view to specializing in midwifery and gynaecology. I did one H.P. and one H.S. job, and then settled down to work for the Fellowship, my intention being to complete that before doing the year's work in midwifery and gynaecology necessary to qualify for entrance for the M.R.C.O.G. examination. I was called up in August, 1939, being due to sit for the Fellowship the following January. Owing to circumstances beyond my control I was not able to continue study, but later, while overseas in 1942–3, took out a correspondence course for the Fellowship. On my return to this country a few months before D-Day, when our bombing offensive was in full swing, study again had to be dropped owing to pressure of work.

I wished to put in six months' intensive study to sit for the Fellowship in July, 1946, but am told that no grant can be made to cover this. Instead, the authorities state that I can have a "house" job for six months at £350 per annum, or a "short general refresher course of two weeks' duration, for which a fee not exceeding seven and a half guineas is paid by the Government." Nothing more. Yet I know of two men who were three years behind me in qualifying, who stayed in the E.M.S. until they had obtained the Fellowship, and then entered the Service as specialists, and are therefore eligible on demobilization for Class III jobs at a salary of £550 per annum. Like Col. Evans, I shall have to live (and support my wife) for six months on the large sum I have amassed as "gratuity" and "leave with pay" if I am to stand a reasonable chance of getting the Fellowship. And what of my wife, who has been separated from me by the "exigencies of the Service" for four out of our six years of married life?

I submit, Sir, that I am paying now for the patriotism which led me to "join up." Never again.—I am, etc.,

AMARUS.

Buying and Selling Practices

SIR,—You were wise, in your leading article of Dec. 1, to draw attention to the wider consequences of any restriction which the Minister may seek to introduce on the buying and selling of practices. Carefully avoiding all personalities, I would like, by a considerable effort, to imagine myself a hypothetical, logically minded Socialist Minister of Health. My object is the laudable one of distributing doctors evenly among the people, of seeing that the poor are attended on the same terms as the rich, of co-ordinating hospitals, laboratories, and other institutions, and of seeing that everything connected with medical care is ultimately controlled by myself.

I have to bear in mind that I am dealing with a very conservative-minded profession, of whose highly technical work I am ignorant. They have the reputation of being as stubborn as mules, so it will be better to lead this donkey with a carrot than to urge him with a goad—at any rate until I have him where I want him. I myself am an idealist who has never hankered for wealth, but I firmly believe that every Conservative has his price, for, to me, the pursuit of private gain is synonymous with Conservatism. Now I find myself in a fortunate position. I firmly believe that it is against the public interest for medical practices run by public money to be bought and sold privately, though it seems fair that the present owners should be compensated. Here, then, is the carrot. Everything now falls together. I arrange that a doctor must have about 2,000 patients to make a living; I forbid him to have more than 3,000. Automatically, the doctors in overdoctored areas plead with me to be allowed to practise in the underdoctored districts. As for the hospitals: Should they beg for pennies in the street? Is it right that the workers should have to join these voluntary contributory schemes? Obviously the State should accept this responsibility. And so—he who pays the piper calls the tune; fortunately and inevitably. All hospital staffs should be paid—why should they give their services? This is pauperism. They shall be paid—by me. Fixed salaries—and that will be the end of this Harley Street racket. What a simple and subtle scheme I have devised! I compensate the doctors; I compensate the hospitals. I just give—which is more blessed than to receive. I need do nothing else for the whole thing to adjust itself.—I am, etc.,

Ashtead, Surrey. W. EDWARDS, M.D.

Obituary

SIR DAVID GALLOWAY, M.D., F.R.C.P.Ed.

We regret to report the death in his 85th year of Sir David James Galloway, which it is now known took place on March 5, 1943, at his home at Johore Bahru, Malay Peninsula. Sir David had a most distinguished and varied career in Malaya—outlying parts of the British Empire which furnish opportunities for medical men of his calibre. He was born in 1858 in Edinburgh, and educated at Daniel Stewart's College and the University of Edinburgh. He took the M.B., C.M. degrees in 1884, the M.D., with gold medal for his thesis, in 1900, and in 1903 was elected to the F.R.C.P.Ed., having become a Member of the College in 1899.

He went out to the Straits Settlements as early as 1885 to practise medicine, and by 1895 his rapidly growing reputation as a physician led to his appointment to accompany the Sultan of Johore on his visit to England in that year. For his services he received the Second-class Order of the Crown of Johore, and in 1914 he was promoted to the First Class for services to the Johore State. Among other responsible positions held by Sir David may be mentioned service as Unofficial Member of the Executive Council of the Straits Settlements in 1903–14 and 1921, vice-chairman of the Straits Opium Commission in 1908, president of the Royal Asiatic Society Straits Branch, and member of the Council of the College of Medicine, Singapore, in which for years he lectured on the principles and practice of medicine. In January, 1924, he was knighted for his many public services, and on his retirement from active work he decided to make his home in the country he had served so long and faithfully, among his many friends. He published papers in this and other journals on splenic abscess of malarial origin, the aetiology and treatment of sprue, otomycosis, and other tropical diseases.

Sir David Galloway was a member of the British Medical Association for fifty years, and held office as president of the Malaya Branch in 1928–9. He represented his Branch at the Birmingham Annual Meeting in 1911 and at the Edinburgh Meeting in 1927.

W. S. DIGGLE, M.Ch.Orth., F.R.C.S.

Mr. Walter Saxon Diggle, whose early death took place on Nov. 17, had made a name for himself as an orthopaedic surgeon in the North-West of England. He studied medicine at the University of Liverpool, graduating M.B., Ch.B. in 1931, and obtained the degree of M.Ch.Orth. in 1936, a year after taking the F.R.C.S. His first appointments were as house-surgeon at the Liverpool Royal Infirmary and surgical registrar at the Northern Hospital; he then became supervising surgeon to the Oakmore Rehabilitation Centre under the Miners' Welfare Committee, and orthopaedic surgeon to the Walton Hospital, to the Bootle General Hospital, and to the Warrington Infirmary. In 1944 he was elected to the staff of the Royal Liverpool United Hospital.

A colleague writes:

The premature death of Walter Diggle has written *finis* to a career only half completed. Had he not been afflicted with the disease which so quickly and remorselessly exacted its ransom he would certainly have achieved a position of eminence and authority in his chosen specialty of orthopaedics; not that his ambitions lay in that direction. His only concern was to do his work honestly and well, and although he could delight his friends and students with frank and humorous expositions of his ideas, he seldom sought a wider audience. Those of us who were privileged to be his friends will have many happy memories of Diggle and one sad, splendid memory of a brave man facing a death sentence with almost unbelievable courage. Perhaps what will be remembered most is his uncompromising hatred of shams and hypocrisy. He was a stalwart champion of straight thinking and straight talking. He was never in two minds about his own opinion on any subject, but would listen readily, almost eagerly, to an opposite view, ready to laugh it to scorn if he could expose its falsity or to change his own view if convinced by the force of an argument new to him. He lived his life to the full, worked hard, played hard. He seemed to bring a breath of fresh air into the company when he joined it. It seems hard to realize that his boisterous laugh is now stilled for ever.

Diggle had, in the short space of ten years, established a wide connexion in hospital and private practice in Liverpool, Bootle, Warrington, and St. Helens. A year ago came his appointment to the teaching school of the Royal Liverpool United Hospital, and the fact that he was given senior rank without a preliminary period of assistantship was a high tribute to the reputation he had established. He was on the threshold of great achievements, and his untimely death has robbed us of a well-loved friend. He leaves a widow and a young daughter

DONALD DUFF, F.R.C.S.Ed., F.R.F.P.S.

We regret to announce the death on Nov. 25 of Mr. Donald Duff, the well-known Glasgow surgeon, who gave outstanding service at the Royal Infirmary as a member of the visiting staff for many years, and afterwards on the Board of Management.

Donald Duff was born in Glasgow in 1873 son of Murdoch Duff, and was educated at Daniel Stewart's College, Edinburgh, and St. Mungo's College, Glasgow. He took the Scottish triple qualification in 1901, the F.R.C.S.Ed. in 1904, and the F.R.F.P.S.Glas. in 1905. He was elected surgeon and gynaecologist to the Glasgow Central Dispensary in 1907 and assistant gynaecologist to the Glasgow Maternity Hospital in 1911, and for ten years held the chair of physiology at St. Mungo's College. During the war of 1914–18 he was a surgical specialist in the R.A.M.C., and consulting surgeon to the Malta Command with the rank of major. After his return to civilian practice he was appointed surgeon in charge of wards at the Glasgow Royal Infirmary and visiting surgeon to the Bellahouston Hospital under the Ministry of Pensions. He lectured in clinical surgery at the University, and examined for the Royal Faculty of Physicians and Surgeons and for the Scottish Conjoint Board; he was a Fellow of the Association of Surgeons of Great Britain, of the Glasgow Northern Medical Society, and of the Medico-Chirurgical Society of Glasgow. He took a particular interest in bone surgery and abdominal surgery, and published many papers on these subjects, including one in these columns in 1922 on the treatment of ununited fractures by bridge grafts. On his retirement from the active staff of the Glasgow Royal Infirmary in 1938 he was elected consulting surgeon.

R. D. GILLESPIE, M.D., F.R.C.P.

Dr. F. O'Donnell Finigan writes from Bampton, N. Devon:

The untimely death of Dr. R. D. Gillespie has left a void in psychiatry and British medicine which will be felt for years to come as a loss sustained by the whole profession. His reputation and original fertile influence extended to every corner of the globe and, possibly, he was regarded even more highly in America than in his native land: his name was almost a household word in Continental medicine.

Dr. Gillespie's graciousness and kindliness, his humility and greatness were appreciated by all who knew him, whether as patient, friend, or colleague. Having known him as a colleague and friend one is apt to forget the brilliance of his attainments. By the age of 28 he had reached senior consultant rank, and from then on he rose from height to height for nearly twenty years. Among his innumerable friends and admirers the opinion has been expressed that there is no man of sufficiently great calibre on whom his mantle might fall. Profoundly impressive also has been the deep sadness and sense of personal loss expressed by his patients—a loss seeming to go deeper than is usually felt by patients after the death of even the most beloved physician. It has been stated sometimes that he had about him some "other-worldness" as though through him something shone from another sphere. He himself seemed to be quite unaware of this, but all who came in contact with him sensed it and left feeling the richer.

The world, and in particular this island, is the poorer for his passing; nevertheless it may be that his memory will act as a spur to renewed effort in the field of psychiatric research, and thus in death he may achieve even more for his beloved science and people than he did during his lifetime. It is for those who received their early encouragement from him, and for all who remain, to carry forward his ideals, sensing that fidelity to this cause may lead them to the mountain peak which "R. D." so often referred to in allegory. This would be a living memorial such as he himself would have wished.

News has been received of the death of Capt. **Kenneth Daniels**, R.A.M.C., in a prisoner-of-war camp in Borneo on Aug. 6. He studied medicine at Newcastle-upon-Tyne, and graduated M.B., B.S. of Durham University in 1929. A member of the Portsmouth Division of the B.M.A., he was in partnership at Copnor before the war, and soon after joining up in 1939 was sent to Singapore Military Hospital. He became medical officer at Kuala Lumpur until the fall of Malaya, when he managed to make his way back to Singapore; as the Japanese approached he escaped to Java, where he was eventually taken prisoner. "C. R." writes: The death of Kenneth Daniels will be felt among a very large circle of friends and patients. His "happy-go-lucky" spirit and his charming boyish manner endeared him to all. He leaves behind the memory of a very fine and painstaking doctor, a great gentleman and a brave man. The greatest sympathy will be extended to his widow, who has borne the separation bravely, the more so when little or no news could be had of him. She had hoped that "no news was good news," it was *not* to be.

Lieut.-Col. **William Byam Lane**, C.I.E., C.B.E., I.M.S. (ret.), died on Nov. 20, aged 79. He was educated at Christ's Hospital, London, at Neuenheim College, Heidelberg, and at St. Bartholomew's Hospital, and qualified with the M.R.C.S. and L.R.C.P. in 1888. In the same year he entered the Indian Medical Service, and soon saw active service with the Hazara Expedition in 1891, in Waziristan in 1894–5, and with the Chitral Relief Force in 1895; for each of these he received a medal with clasp. Soon after he entered the Jail Department, and was promoted to be Inspector-General of Prisons in the Central Provinces from 1905 to 1916. His reputation as a sound administrator led to his being chosen for the important work of Inspector of the Disciplinary Labour Corps, Mesopotamia Expeditionary Force, in 1916; in 1920–1 he held the post of Inspector-General, Civil Jails, Mesopotamia; and from 1919 to his retirement in 1921 he was Acting Director of Health Services, Mesopotamia. For his valuable work in those responsible positions Col. Lane was awarded the C.I.E. in 1918 and the C.B.E. in 1919. After his retirement he lived in London, and in 1925–6 held the honourable position of Master of the Mercers' Company. He joined the British Medical Association on qualifying in 1888 and retained his membership for 58 years. He was a thoroughly sound and much-respected officer of the I.M.S. who will be mourned by his many friends.

The Services

A meeting will be held at the Duke of York's Headquarters (Centre Block), Chelsea, on Wednesday, Dec. 19, at 6.30 p.m., of officers who served in the 17th (1st County London) General Hospital, Territorial Army, to discuss the question of an annual dinner.

Capt. A. R. T. Lundie, R.A.M.C., has been awarded the M.C., and Capt. H. Mannington, R.A.M.C., has been mentioned in dispatches, in recognition of gallant and distinguished services in the field.

The following have been mentioned in dispatches in recognition of gallant and distinguished services in Italy: Brig. (Temp.) S. Arnott, C.B.E., D.S.O., and Col. C. H. K. Smith, O.B.E., M.C., late R.A.M.C. Brig. (Temp.) W. M. Cameron, O.B.E., Brig. (Acting) J. Kinnear, O.B.E., T.D., and Brig. (Local) F. A. R. Stammers, C.B.E.; Cols. (Temp.) W. A. D. Drummond, T. D. Inch, C.B.E., M.C., T.D., W. A. Y. Knight, A. S. Pern, O.B.E., T.D., and W. L. Spencer Cox, O.B.E., M.C.; Col. (Acting) J. T. Robinson; Lieut.-Cols. (Temp.) H. J. B. Atkins, T. F. Briggs, J. B. Herman, R. Johnston, D. W. E. Lloyd, M.C., C. M. Marsden, J. B. McEwen, M.C., J. S. Miller, T. P. Sewell, E. G. Sibley, W. R. Sprunt, T.D., A. W. S. Thompson, O.B.E., C. S. Thomson, A. P. Trimble, A. S. Wesson, P. L. E. Wood, D.S.O., M.B.E.; Majors H. F. Anderson, R. L. Benison, A. D. C. S. Cameron, R. G. Davies, E. A. Fiddian, C. Kenton, W. McLeod, R. M. Paton, M. S. Williamson, M.C., and G. H. Wooler; Major (Temp.) A. Beardwell, D. Bell, A. B. Birt, R. W. Cope, S. H. Croot, D. H. Cummack, H. W. Davis, A. C. Dornhorst, T. Duncan, K. B. Gibson, A. M. Giles, R. E. Haswell, J. Howell, M. A. Jones, A. R. Kennedy, T. G. Lowden, L. G. Macfarlane, W. B. McKenna, R. J. Milbank, R. I. Mitchell, A. A. Murray, W. M. Owen, J. H. Patterson, W. A. V. Payne, K. R. D. Porter, M.B.E., H. E. Smith, R. S. Stevens, D. L. Stewart, A. M. Tait, R. B. Terry, A. J. Thomas, J. H. Vickers, M. A. G. Ward, J. H. Warren, M.B.E., and G. N. Wilson; Capts. E. S. Aiello, J. W. Clark, S. A. Cohen, H. J. S. Coldham, J. Comyn, A. Fearnley, D. Ferguson, R. Fletcher, N. E. France, C. B. Hinckley, B. L. Hoffmann, M. S. Howe, M.C., P. H. Jones, W. A. D. Jones-Roberts, M. Latner, R. S. Lawrie, R. T. S. Louttit, B. S. Lush, J. Macdonald, A. F. J. Maloney, J. F. Mawe, R. P. Maybin, R. I. McAlley, A. D. McGill, J. D. McGregor, N. C. Mond, M. E. Moore, N. P. Orchard, A. T. Pagan, A. Paterson, D. E. Paterson, D. Purdie, E. E. Rawlings, J. J. Reeks, J. W. Richmond, J. F. Robertson, F. H. Robson, L. C. Robson, H. D. Rossiter, R. P. G. Sandon, J. Scott, H. A. Shaw, J. R. S. Shields, E. C. S. Talbot, J. E. Tannian, A L. Tulk, E. Vure, A. S. Walker, J. S. Walters, D. Weitzman, F. J. Whitaker, and A. L. Wyman; Capt. (Temp.) F. de B. White; Lieuts. W. H. Chanter, N. Dancer, J. R Grice, W. Hawthorne, F. H. Hogarth, R. J. Holliday, J. Noble, J. R. Purvis, E. A. Williams, and C. D. Woodhead, R.A.M.C. Col. M. Kirk Bryce; Col. (Temp.) D. Datt; Lieut.-Cols. (Temp.) C. W. Greene and W. Major G. Singh, Jaipur Medical Services. Col. J. R. Boyd, C.B.E., M.C., New Zealand Military Forces.

CASUALTIES IN THE MEDICAL SERVICES

Killed in action or died on active service.—Capts. Robert William McNamara and Adiel Elad Hazael Reid, R.A.M.C., and Flight Lieut. Hugh Macivor Given, R.A.F.V.R.

Died.—Capt. William Thomson, M.C., I.A.M.C.

Previously reported missing, now known to have been killed in action at Alexandra Hospital, Singapore, on Feb. 14, 1942.—Lieut. Geoffrey Rogers, R.A.M.C.

Killed in air accident.—Major Harry William Gilbert Staunton, I.M.S.

DEATHS IN THE SERVICES

Capt. **George Peter Nash**, R.A.M.C., died in Brussels of diphtheria on Nov. 23 when on his way home for demobilization. He was born in Canada, and qualified in 1932 from Queen's University, Ontario. He had only been just over a year in practice at Oxford when he sought a commission in the R.A.M.C. He was in the landings at Sicily, Salerno, and Anzio. He leaves a widow and two small sons. The news of his tragic end when so near home after over five years of service was received with profound regret by his colleagues in Oxford, who extend their sincere sympathy to his widow and young children.

Universities and Colleges

ROYAL COLLEGE OF PHYSICIANS OF LONDON

The Fitzpatrick Lectures on "The History of the English Medical Profession," which were to have been given by Dr. Cecil Wail on Dec. 11 and 13, have been cancelled owing to the illness of the lecturer.

Lord Moran, P.R.C.P., writes: In your issue of Dec. 1 you have printed extracts from a letter addressed to me by the President of the Royal College of Surgeons. It is, therefore, only fair to your readers that I should send you my reply:

Royal College of Physicians,
Nov. 30, 1945.

My dear President,—Thank you for your letter. There are two issues: what is best for the nation, and what is the course which is most likely to help the Royal College of Physicians to discharge its duties to the profession in the years to come. If I may dispose of my second question forthwith, I think you will agree that the only body that can answer such a question is the Comitia of the College. The Comitia decided on Oct. 25, with only two dissentients, that at the present time the College must remain where it is. I tell you this because I feel that it would be unfair to your Council if they were left in doubt about the actual feeling of the Fellows of my College. And I may add that this verdict has been endorsed on practical grounds by a Committee of independent experts.

May I then pass to consider whether that decision is at variance with the national interest? Most Fellows of this College have yet to be convinced of the precise benefit to the State if they were to abandon a building where they have long been the guests of the Crown, a building which for them has treasured historic associations, in order to migrate at a very difficult time so that they might live nearer to the sister College. It is, incidentally, common ground that if the Royal Colleges should ever decide on a common site (and the resolution of the Standing Joint Committee to which you refer spoke of a common site, and not of any particular site, such as Lincoln's Inn Fields) each College would retain its identity.

I am anxious to say nothing which may make it more difficult for my College to work together with our surgical friends, but this should be said. The consultant service of the future will inevitably bring all sections of consultants and specialists into more intimate co-operation, and the new responsibilities that will necessarily fall on the three Royal Colleges in connexion with that service will give them a unity of purpose which will not be dependent on geography. Meanwhile, it can only be hurtful to the natural development of a friendly partnership of that kind to refuse to accept the decision of the Comitia, and to ignore the very weighty reasons which made that decision inevitable. "When friends plan and do together, their minds become one mind and the last secret disappears." What is needed is a common purpose. In the coming months the Royal Colleges will have an opportunity of serving the nation by pooling their resources and their wits to give it a really efficient consultant service. If that opportunity is taken we need not fear that a real partnership of the Royal Colleges will fail to come into being.

Yours sincerely,
MORAN.

UNIVERSITY OF OXFORD

In a Congregation held on Nov. 24 the degree of D.M. was conferred, in absence, on J. C. Ryle.

UNIVERSITY OF CAMBRIDGE

Sir Lionel Whitby gave his inaugural lecture as Regius Professor of Physic on Dec. 5. Its title was "The Science and Art of Medicine."

The report of the Financial Board on allocations from the University Chest to the several funds states that in the published estimates no account is taken of the Treasury grant of £15,000 for medical purposes. Since it is necessary for a separate account to be kept of the expenditure of this grant, it will be credited to a Medical Grant Fund, from which allocations may be made direct to the medical departments concerned.

At a Congregation held on Nov. 23 the following medical degrees were conferred:

M.D.—E. E. Pochin, G. E. Parker, I. A. Guest.

M.B., B.CHIR.—*D. A. N. Barran, *R. Bellamy, * D. N. Seaton, *R. V. Walley, *J. A. Waycott, *E. J. M. Weaver.

* By proxy.

UNIVERSITY OF LONDON

At a meeting of the Senate, held on Nov. 28, Walter Freudenthal, M.D., was appointed to the University readership in dermatological histology tenable at University College Hospital Medical School as from Oct. 1.

The title of professor emeritus in morbid anatomy in the University was conferred on G. W. de P. Nicholson, M.D., who was University professor of morbid anatomy at Guy's Hospital Medical School from 1922 until April, 1944.

The *University of London Gazette* dated Oct. 12, only recently received, announces that the Wellcome Trustees are giving to the University an endowment of £44,000 to provide for the institution of a part-time Chair of Tropical Medicine to be held at the London School of Hygiene and Tropical Medicine.

An Institute of Child Health has been set up, at which will be tenable the Chair of Child Health recently established through the generosity of the Nuffield Foundation. For the time being the institute will be a central activity of the University and will be given facilities for its work both at the Hospital for Sick Children, Great Ormond Street, and at the British Postgraduate Medical School at Ducane Road. Eventually the institute will form part of the federation of postgraduate medical institutions in London, the scheme for which is now being worked out.

The following have been recognized as teachers of the University in the subjects indicated in parentheses: *London (R.F.H.) School of Medicine for Women:* Dr. W. G. Scott-Brown (Laryngology and Otology); Dr. Mary M. Shaw (Venereal Diseases); Dr. Ursula Shelley (Paediatrics); Dr. Ernest T. D. Fletcher (Medicine); Dr. Emma C. Williams and Dr. Lucy Wills (Chemical Pathology). *St. Thomas's Hospital Medical School:* Dr. C. B. B. Downman (Physiology). *St. George's Hospital Medical School:* Dr. R. D. Teare (Forensic Medicine). *King's College:* Dr. J. A. C. Knox (Physiology).

The appointments of house-physician at Southmead Hospital, Bristol, and medical clinical assistant at Sheffield Royal Infirmary have been approved for the purposes of the M.D. examination (Branch I).

The reduction in the clinical course for the M.B., B.S. examination from 36 to 30 months is to be continued up to the end of the session 1945–6, but the question of continuing it after that date will be considered this month.

An additional M.B., B.S. examination will be held in 1946, beginning on Monday, Jan. 28.

Medical Notes in Parliament

Postgraduate Courses for R.N. Doctors

Mr. A. V. Alexander explained on Nov. 16 that postgraduate medical courses up to six months' duration were provided for medical officers of the Royal Navy who were making their career in the Navy, so that they might be of greater use in their subsequent service. To throw open these courses to R.N.V.R. doctors would involve additional expense which he did not consider justified in view of the fact that the careers of these officers lay outside the Service.

The Navy's Ratio

Mr. Alexander stated on Nov. 19 that the present ratio of medical officers in the Navy to personnel was nearly 3 per 1,000. The present proportion of doctors to the civil population was 0.7 per 1,000. Conditions in the Royal Navy so differed from those in civil life that true comparison was impossible. Duties of Naval doctors included treatment of Merchant Navy personnel in certain ports.

Medical Demobilization

Replying on Nov. 20 to questions on the demobilization of medical officers, Mr. Isaacs said the number to be released in Class B in the medical profession, as in other professions, was necessarily limited. Within this limited number the Central Medical War Committee was able to deal with the cases where the need was most urgent, knowing the position over the country as a whole. Release of medical officers in Class A proceeded concurrently with release in Class B. He did not think it appropriate to interfere further with the Class B scheme. Col. Stoddart-Scott said the Central Medical War Committee was allowed to recommend only 33 medical officers monthly for demobilization under Class B, although over 100 cases worthy of recommendation came before it each month.

In a statement circulated on Nov. 21 Mr. Dugdale gave the following target dates of releases of medical officers in the Royal Navy: Groups 17 to 20, Dec. 31, 1945; 21 and 22, Jan. 31, 1946; 23 and 24, Feb. 28, 1946; 25 and 26, March 31, 1946 A tentative further forecast for medical officers was: Groups 27 to 29, April 30, 1946; 30 to 32, May 31, 1946; 33 to 35, June 30, 1946. Target dates were also given for dental officers.

Blood Tests in Motorists

In reply on Nov. 22 to Col. Gomme-Duncan, Mr. Ede said the law made no provision for blood tests to be taken compulsorily in a case where a motorist was suspected of being under the influence of drink. He was not aware of any cases in which these tests had been made on the instructions of the police. Where samples of blood had been taken from a motorist this had been done at the motorist's express request. It was open to a motorist to arrange for a separate analysis to be made; the difficulty would be to ensure that the analysis related to samples of blood taken from the defendant at the same time.

Mr. MANNINGHAM-BULLER asserted that it was a fairly regular practice in the Midlands for samples to be taken from suspected persons when in hospital with injuries sustained in a motor accident. He suggested that where blood samples were taken duplicate evidence should be given to the suspected person. Mr. EDE said that if the police did take such samples it would have to be the subject of some regulation so that the defendant could produce his own independent evidence. He was not convinced it was necessary to give the police this power in England. A practice of the kind prevailed in some of the United States.

Women Medical Students

Replying on Nov. 22 to Mr. Peter Freeman, Mr. BEVAN said the Government had made it a condition of future grants to medical schools that a reasonable proportion of women students should be admitted. Medical schools which had not previously admitted them were making plans to do so as soon as the difficulty of providing the necessary additional accommodation could be overcome.

Health of British Forces in Germany

There is no indication of an increase of cases of infectious diseases in the British Zone in Germany. An epidemic control system has been established on the borders of this zone.

After consideration by the Army Pathology Advisory Council on behalf of all three Services it has been decided not to immunize against diphtheria the British Forces generally in Germany. All medical and attached personnel in medical units are immunized where necessary after Schick testing. In the event of outbreaks steps will be taken to immunize all at risk.

Mr. Dalton on Doctors

On Nov. 27, during a Finance Bill discussion about the taxation of motor cars and of petrol, Mr. DALTON said that if the petrol duty were increased all sorts of people would claim rebates, including the doctor, who used his car in the course of his profession. The Government would give bits of paper to doctors or commercial travellers entitling them to get their petrol cheaper. These would be "traded" and the Government would not be able to control this black market.

The House agreed to the duty on cylinder capacity as proposed in the Bill.

Private Practice and Colonial Medical Service

Answering an inquiry on Nov. 28 by Col. Dodds-Parker, Mr. GEORGE HALL recorded that since the Colonial Medical Service was instituted in 1934 no officer appointed to it had a right to engage in private practice. In many cases officers were allowed to do so as a privilege under conditions governed by local regulations. Differences in local circumstances and in previous custom led to a wide variation in the procedure hitherto adopted in the different Colonies. He had now under consideration proposals which would lead to much greater uniformity.

Professional Subscriptions

When the House of Commons was in Committee on the Finance Bill on Nov. 29 Colonel ERROL moved that any amount not exceeding £15 in any year, which was paid by a taxpayer as subscription to an institution or other body conducted mainly for the advancement of any branch of learning, science, or technology and not operated for profit, should be deducted from the taxable salary, fees, or emoluments of such a person. He said these subscriptions were a burden to young men struggling to make their way in a profession. Mr. LINSTEAD said that the independent practitioner was entitled to deduct subscriptions which he paid to scientific societies if necessary in the practice of his profession. The man who happened to be an employee was not allowed to deduct them.

Sir FRANK SOSKICE said the practice differed under Schedule D and Schedule E. The former was more generous. Mr. Dalton was considering the discrepancy. He could not accept Colonel Errol's proposal. The proposed new Clause was negatived.

Committee on Scientific Man-power and Resources

Mr. ATTLEE announced on Nov. 29 that the Government had decided to appoint a committee of leading scientists and others to consider the policies which should govern the use and development of British scientific man-power in the next ten years. He was asked by the committee to submit an interim report on broad lines at an early date. Man-power was the most urgent problem. The committee would start its inquiry at once under the temporary chairmanship of Sir Alan Barlow.

Nurses in Mental Institutions: Government Regulation.—During the debate on Nov. 20 on the second reading of the Emergency Laws (Transitional Powers) Bill, Mr. W. S. MORRISON pointed out that it prolonged temporary laws for two years. The schedule of the Bill included Regulation 22AB, which gave power to require nurses, etc., to continue in employment in mental institutions. Why should the Minister of Health have this power? There was no doubt that compulsion would be needed for the unhappy purpose of staffing these mental institutions in the next two years. Mr. EDE said that Regulation 22AB had received a surprising amount of attention. A considerable number of the male staff of mental institutions were non-commissioned officers who had served in the Army. There was still a shortage of these men. Until they came back it was necessary that the people who took their places should be retained in employment. The Order did not apply only to male nurses, but the serious shortage was in respect of them. He hoped the Regulation need not be enforced through the whole period to Dec. 31, 1947. The Bill was read a second time.

T.T. Milk in Schools.—On Nov. 22 Miss WILKINSON said that under the Regulations for the Provision of Milk and Meals, 1945, the source and quality of school milk must be approved by the medical officer of health. Subject to this no exception was taken by her Department to the supply of tuberculin-tested milk to schoolchildren if heat-treated milk was not available or, in other cases, if no extra expense was involved. There were no medical grounds on which she would be justified in encouraging the supply of tuberculin-tested milk in preference to heat-treated milk.

Beds for Tuberculosis in Scotland.—At June 30, 1945, the latest date for which information is available, local authorities in Scotland had 1,898 tuberculous patients on their waiting lists and 5,470 patients under institutional treatment. The total number of beds available is approximately 6,700. The difference is accounted for mainly by the number of beds, estimated at 500, for which no nurses are available, and the number of beds in private sanatoria.

Medical News

On his 80th birthday, Nov. 28, 1945, a silver rose bowl was presented to Dr. H. G. Adamson by thirty of his old assistants and house-surgeons in the skin department of St. Bartholomew's Hospital at a sherry party held at Dr. Henry Corsi's house in Harley Street. Subscriptions had been sent by his old pupils from places as far apart as Australia, South Africa, and East Africa. In spite of the difficulties of the present time some sixteen of the subscribers attended the party to pay tribute to their old teacher, whom they were glad to see looking hardly a day older than when he retired from St. Bartholomew's Hospital eighteen years ago.

The Long Fox Lecture will be delivered at 8.15 p.m. on Tuesday, Dec. 11, in the main lecture theatre of the Wills Physical Laboratory (Royal Fort), Bristol University, by Prof. M. Skene, D.Sc. Subject: "Substances controlling Plant Growth."

The Royal Surgical Aid Society will hold its 83rd annual meeting at the Mansion House on Wednesday, Dec. 12, at 4 p.m., with the Lord Mayor of London in the chair.

Dr. C. J. Blok, chief pharmacist to the University and Municipal Hospitals, Amsterdam, will give a lecture on "Pharmaceutical Conditions in Holland under the German Occupation" before the Pharmaceutical Society of Great Britain (17, Bloomsbury Square, W.C.), on Thursday, Dec. 13, at 7 p.m.

On Thursday, Dec. 13, at 8 p.m., at the Royal Society of Tropical Medicine, 26, Portland Place, W., the American Ambassador will present to Dr. C. M. Wenyon, F.R.S., the Theobald Smith gold medal, awarded to him by the American Academy of Tropical Medicine.

A meeting of the London Association of the Medical Women's Federation will be held at B.M.A. House (Tavistock Square, W.C.) on Friday, Dec. 14, at 8.30 p.m., when Miss D. J. Kinloch Beck, F.R.C.S., will speak on "The Scope of Neurosurgery."

A lecture entitled "A Criticism of Physical Medicine" will be given by Sir Morton Smart on Saturday, Dec. 15, at 3.15 p.m., at the Royal Institute of Public Health and Hygiene, 28, Portland Place, W. Mr. V. Zachary Cope, president of the Board of Registration of Medical Auxiliaries, will take the chair. Physiotherapists and students of physiotherapy are invited, but admission will be by ticket only, which can be obtained from the honorary secretary, Society of Physiotherapists, 24, South Molton Street, London, W.1.

At the 283rd anniversary meeting of the Royal Society held on Nov. 30 Sir Henry Dale, O.M., gave his presidential address; Sir Robert Robinson was elected as his successor, and a portrait of the retiring president by Mr. James Gunn was unveiled.

The annual meeting of the Empire Rheumatism Council will be held at 11, Chandos Street, London, W.1, on Thursday, Dec. 13, at 4.30 p.m., when the chairman, Lord Horder, will present the annual report.

On Oct. 20 (p. 543) Sir Arnold Lawson, president of the Royal Medical Benevolent Fund, made a moving appeal for contributions to the Christmas Gifts Fund. Readers who meant to respond but have not yet done so are asked to send their contributions marked "Christmas Gifts" to the Secretary, R.M.B.F., 1, Balliol House, Manor Fields, Putney, S.W.15.

Visiting hospitals and medical centres in Britain for the next three weeks are the following Norwegian doctors: Dr. Kristian Kristiansen, Neurological Department of Oslo University Clinic; Dr. Hans Frederik Fabritius, Municipal Hospital, Oslo; Dr. Alf Brodal, University of Oslo; and Dr. Per Hanssen, Oslo Municipal Hospital. The visit has been arranged by the British Council.

The American Association for the Study of Goiter again offers the Van Meter prize award of 300 dollars and two honourable mentions for the best essays submitted concerning original work on problems related to the thyroid gland. The award will be made at the annual meeting of the Association in Chicago, in April or May, 1946, providing essays of sufficient merit are received. The competing essays may cover either clinical or research investigations; should not exceed 3,000 words in length; must be presented in English; and a typewritten double-spaced copy sent to the corresponding secretary, Dr. T. C. Davison, 207, Doctors Building, Atlanta, 3, Georgia, not later than Feb. 20.

The National Association for the Prevention of Tuberculosis has appointed Major Eric Wittkower, R.A.M.C., to conduct an investigation into the psychology of tuberculosis, and he will take up this work on his release shortly from military service. The research will begin with careful case histories and personality studies on a number of tuberculous patients.

The Food Group of the Society of Chemical Industry has issued from 56, Victoria Street, London, S.W.1, its syllabus for the remainder of the session 1945-6. All meetings are to be held in London, except joint meetings with the Yorkshire section at Leeds on Dec. 15, and with the Edinburgh section on Jan. 24.

To meet the increased demand for essential medicinal supplies during the winter months the Minister of Food has decided to authorize a temporary increase in allocations of sugar for the preparation or manufacture of medicines in accordance with formulae of the *British Pharmacopoeia, British Pharmaceutical Codex*, and *National War Formulary* during the period ending Jan. 5, 1946. The amount of the increase is 5% of the usage of sugar for this purpose during the twelve months ended June 30, 1939.

EPIDEMIOLOGICAL NOTES

Discussion of Table

In *England and Wales* whooping-cough, diphtheria, and scarlet fever were more prevalent, increasing by 85, 73, and 53 cases respectively. Decreases were recorded for acute pneumonia 43, measles 42, and dysentery 32.

Scarlet fever and whooping-cough followed similar trends during the week; the general picture was one of small rises in the north and south with fewer cases in the midlands.

Diphtheria had its highest incidence for 85 weeks; rises were recorded in Lancashire 41, Northumberland 17, Yorks West Riding 16, London 11, and Middlesex 11. Notable decreases were in Warwickshire 25, and Durham 18.

Measles was prevalent only in Norfolk, Norwich C.B. 56; one-seventh of the total cases in the country were notified in this city.

Dysentery fell to the lowest level for the past forty-six weeks. The chief returns were London 37, Lancashire 22 (Liverpool C.B. 11), Gloucestershire 19 (Bristol C.B. 18), Yorks West Riding 14, and Glamorganshire 12.

In *Scotland* infectious diseases were less prevalent. The falls in notifications included primary pneumonia 51, scarlet fever 40, whooping-cough 20, dysentery 20, cerebrospinal fever 13. The only increase was one of 26 for diphtheria, this rise being confined to the south-eastern and western areas.

In *Eire* diphtheria rose by 14, and whooping-cough fell by 20, while enteritis and diarrhoea remained stationary with 50 cases, of which 33 were notified in Dublin C.B.

In *Northern Ireland* there were 9 fewer cases of diphtheria, and 6 more notifications of scarlet fever.

Week Ending November 24

The notifications of infectious diseases in England and Wales during the week included: scarlet fever 1,911, whooping-cough 1,232, diphtheria 654, measles 453, acute pneumonia 579, cerebrospinal fever 32, acute poliomyelitis 15, dysentery 223, paratyphoid 10, typhoid 7, typhus 2.

No. 46

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended Nov. 17.

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for: (a) England and Wales (London included). (b) London (administrative county) (c) Scotland. (d) Eire. (e) Northern Ireland.

Figures of Births and Deaths, and of Deaths recorded under each infectious disease, are for: (a) The 126 great towns in England and Wales (including London). (b) London (administrative county). (c) The 16 principal towns in Scotland. (d) The 13 principal towns in Eire. (e) The 10 principal towns in Northern Ireland.

A dash — denotes no cases; a blank space denotes disease not notifiable or no return available.

Disease	1945					1944 (Corresponding Week)

ANY QUESTIONS?

Diphtheria Immunization

Q.—*A child was immunized three years ago with A.P.T., 0.1 c.cm. and then 0.5 c.cm. one month later. It is now said that the correct dosage is 0.2 c.cm. and then 0.5 c.cm. Should the child be re-immunized with two doses in view of this, or would one boosting dose be sufficient?*

A.—The defect in the immunization course described is the possible inadequacy of the primary stimulus to the immunity mechanism. A single reinforcing dose might give all the response that is required, but, in view of the long interval, it would probably be better to give a complete course consisting of two spaced doses of 0.2 c.cm. and 0.5 c.cm. of A.P.T.

Hepato-renal Syndrome

Q.—*What is the hepato-renal syndrome and how is it related to the state described as cholaemia? What is the best treatment for a patient with liver disease who seems in danger of passing into the state of hepatic (? hepato-renal) failure?*

A.—The name "hepato-renal syndrome" is sometimes loosely applied to any condition in which there is simultaneous insufficiency of the liver and the kidneys; examples of this are Weil's disease and carbon tetrachloride poisoning. If the term is used in this sense it becomes so comprehensive as to be almost meaningless. The name "hepato-renal syndrome" is therefore better confined to conditions in which primary hepatic disease is followed by signs of renal failure. The syndrome in its classical form is seen after operations on the gall-bladder or biliary tract and after mechanical injuries of the liver. It may, however, occur with any severe hepatitis or necrosis of the liver. It is not generally appreciated that degenerative changes of varying degree are always found in the kidneys of patients dying from acute infective hepatitis and homologous serum jaundice. The lesions range from simple cloudy swelling to actual necrosis, similar to that of mercurial poisoning, and they are classified by the pathologist as cholaemic nephrosis. Similar renal changes are found after death in the hepato-renal syndrome, and we might therefore define the syndrome as cholaemia plus cholaemic nephrosis.

There are two schools of thought about the mechanism of production of the renal damage. It is similar to the renal damage which results from the crush syndrome, gas gangrene, and incompatible blood transfusion. One school ascribes it to the action of toxic substances, such as products of digestion, which are detoxified in the normal liver, products of liver autolysis, and the toxins of micro-organisms in the liver or the biliary passages. The other school ascribes the renal damage, not only in the hepato-renal syndrome but in all these disorders, to vascular shock, dehydration, and failure of the blood supply to the kidney.

The primary objectives of therapy in cholaemia and the hepato-renal syndrome are to repair dehydration and restore the disturbed blood chemistry to normal, to reduce the metabolic load on the liver and kidneys, and to promote the regeneration of cells which have been destroyed. It is desirable to have frequent estimations of the blood urea, blood sugar, plasma chloride, and plasma bicarbonate, and a chart should be kept of the fluid balance. If parenteral therapy is used, the greatest care must be taken to avoid circulatory overloading, oedema of the lungs, or abrupt alterations in the blood chemistry. Glucose should be given freely, by mouth or intravenously. Calcium salts are of value for the relief of symptoms of cerebral irritation. Barbiturates are dangerous and should not be used for intravenous anaesthesia. If there are signs of vascular collapse, transfusion of plasma is probably desirable. So far there will probably be general agreement; controversy arises over the value of treatment with proteins, amino-acids, and choline. Orthodox therapy is to restrict the intake of both proteins and fat, to reduce the work of the liver. Recently there has been a tendency to give a high protein intake, in the belief that proteins may protect the liver from fatty infiltration and necrosis and promote regeneration of the parenchyma. Data are still inconclusive, and the use of protein hydrolysates and methionine must be considered very much an experiment. There is a stronger case for choline chloride, as it is unlikely to do harm if injected slowly, and it is believed to influence the kidneys as well as the liver. A daily dosage of 10 g. has been recommended, and this should be given by slow intravenous drip in normal saline, not exceeding 3 g. choline an hour.

Oral or Injected Oestrogens

Q.—*What are the advantages of injecting synthetic or natural oestrogens into the body over the oral route? Please indicate any diseases or disorders alleviated and corrected by parenteral oestrogens only, and unaffected by oral treatment.*

A.—In giving oestrogens it is important to avoid unnecessarily high dosage and to aim at achieving a continuous action, bearing in mind that small and oft-repeated doses are more effective than large doses given at infrequent intervals. So long as it is efficient, oral administration is clearly preferable, for it not only assures a regular and frequent intake but is more convenient than repeated injections.

Natural Oestrogens.—With the possible exception of oestriol, which is in any case weakly oestrogenic, natural oestrogens are much less effective when given by mouth than when they are injected intramuscularly. Oral preparations are therefore employed when a minimal effect is sufficient, as in the treatment of climacteric symptoms, vulvo-vaginitis in children, etc. When a maximum effect is desired parenteral administration is necessary. Aqueous solutions are quickly absorbed and their action is fleeting, so they are rarely used. Hormone esters (e.g., oestradiol benzoate, oestradiol dipropionate) in an oily medium, which are more slowly absorbed and have a more prolonged effect, are therefore usually employed for therapeutic purposes. They are used in the treatment of uterine hypoplasia, uterine inertia, to suppress lactation, and to induce abortion when the foetus is dead. For such uses it would be difficult to achieve a sufficient concentration of hormone in the blood stream by oral administration alone. In many cases there is much to be said for combining oral and parenteral administration, thus ensuring both a powerful and continuous application of the hormone. Recent developments to achieve these objects are to inject oily suspensions of crystals, and to make subfascial and subcutaneous implants of hormone tablets. Although effective, this latter method is open to the disadvantage that, once applied, the treatment is out of control; it is not easy to find and remove the tablet if it proves to have untoward effects.

Synthetic Oestrogens.—Synthetic oestrogens are not destroyed or inactivated to any extent by the processes of digestion and assimilation, so they are almost as efficient when given by mouth as by injection. Their potency on oral administration is not much less than that of natural oestrogens administered parenterally; some, indeed (e.g., dienoestrol), are more potent. The fact that synthetic oestrogens are cheaper, and that by the oral route alone it is easy to assure the patient of an intake adequate for the treatment of any condition, has led to their present popularity, which has been achieved at the expense of the natural oestrogens. This is perhaps unfortunate, because their high potency is not always appreciated; they are often administered too freely and in too large a dose. Again, they frequently cause toxic symptoms such as nausea, vomiting, and headache (? due to overdosage). There is little, if any, need to give synthetic oestrogens by injection—they are sufficiently active by mouth. Parenteral administration does sometimes seem to decrease their tendency to produce vomiting, but not always.

Furunculosis

Q.—*I would be grateful for advice on an obstinate furunculosis. The patient is a woman of 35, stout and in good condition. Several boils develop together in the external auditory meatus. The patient attributes her condition to wartime feeding.*

A.—This may be a case of boils localized by reason of the character of the skin in which the first lesion arose. In that case appropriate local treatment is most important. The part should be kept dry, and watery solutions, syringing, and ointments should be avoided. Dry heat, as in short-wave diathermy and x-ray therapy, is beneficial. A solution of one of the dyes in spirit, or 10% phenol in glycerin, is also a suitable local measure. It is doubtful if specific therapy, such as penicillin injections, is necessary, but it may be considered, and penicillin may similarly be used as a local application. If the affection is of long standing, then penicillin or vaccines or non-specific shock therapy often help. The patient should be warned against fiddling with the ear.

In a general way chronic boils are dependent upon general health (urine and blood particularly should be examined), a focal source of infection (such as a fissure, running ear, mouth or nose sepsis, pruritus ani), the type of skin and patient (seborrhoeic and hyperhidrotic), and occupation (oil and tar workers, etc.). Even with localized boils this approach is necessary and desirable. Wartime diet is not responsible for boils.

Rubbing the Skin after Subcutaneous Injections

Q.—*What are the indications for, and the rationale of, rubbing or kneading after giving a subcutaneous injection? Is, spirit or iodine swabbed over the surface a few times likely to sterilize the skin? If not, does massage encourage inoculation of the puncture with staphylococci, etc., from the neighbourhood?*

A.—The object of this manœuvre is to disperse the injected fluid and so hasten its absorption. This may be of slight benefit when the fluid is a drug which is required to act as quickly as possible. It is actually contraindicated after the injection of an active immunizing agent, particularly A.P.T. In other circumstances it is merely superfluous. The added risk of infection must be very slight; pressure would tend to produce an outward flow along the track of the needle, and penetration by bacteria from the surface should therefore not occur. Adequate treatment with iodine or spirit does disinfect the skin in the sense of ridding it to a large extent of its "transient" and possibly dangerous flora. It is impossible to destroy the "resident" flora (including staphylococci), but these organisms are usually non-pathogenic.

Test for Death from Drowning

Q.—*When the body of a man who had fallen overboard and been caught up in the boat's propeller was eventually hauled out of the water I noticed that, although no clotting was present (presumably due to the action of sea water), there was no bleeding from any of the severe lacerations. Apart from the length of time the body had been held under water, I concluded from the absence of bleeding that the heart had stopped. Was this correct? If so, could one test for death in cases of drowning by incising a vascular part of the body? If, after squeezing out any stagnant blood from the surrounding parts, no further bleeding occurred, could one assume stoppage of the heart and death? Does a weak pulsation of the heart cause some blood-flow in the arterioles, which could be recognized from an incision? The answer given in these columns that death should be assumed only when rigor mortis had begun to set in shows that a quicker test for death is desirable.*

A.—It can always be assumed that death has taken place when arteries cease to bleed, and the bigger the artery the more definite the proof of death becomes. To make use of this fact in a test for death would be unjustified for several reasons.

Under certain conditions the action of the heart is liable to be so weak that it cannot be observed by ordinary clinical procedures. Such instances commonly occur in cases of hanging, suspected drowning, electric shock, injury by lightning, and in the newly born. In these cases the weak action of the heart may maintain only a very small flow of blood through the vessels. Incising a vascular area, even arteriolar, may reveal a slight ooze of blood only, devoid of pulsation and leading to an erroneous impression of actual death. The incision of a larger artery may indeed indicate whether or not life still exists, but such an operation is unwarranted and may itself precipitate a fatal issue or lead to unnecessary complications. The only procedure in any case of doubt is to continue with resuscitation until breathing is established or death is absolute. In cases of suspended animation from electric shock or lightning this may necessitate the continuance of artificial respiration for two hours or more.

Fatigue and Depression

Q.—*Is there any satisfactory treatment by drugs or diet for fatigue and depression in a male aged 60? All tests are negative, despite a long history of colitis, which has improved with the onset of a synovial hypertrophy in one knee-joint. This knee trouble has itself improved, but the subjective symptoms have increased. Occupation is full-time. Energy runs down rapidly, especially after lunch. Abstainer and smokes tobacco, two ounces a week.*

A.—The difficulty here is mainly one of diagnosis. The commonest cause of such symptoms appearing, in the absence of any abnormal physical finding, would be involutional depression. If this were established the prospects of recovery with electrical convulsion treatment would be excellent. Other possibilities are an anxiety state, possibly brought about by uncongeniality of work or by private affairs, dietetic inadequacies, early cerebral arteriosclerosis, etc. A psychiatric examination is required and reference to a consultant seems to be indicated.

Supraorbital Neuralgia

Q.—*A girl of 22 suffers from right supraorbital neuralgia. Health is otherwise good. Dental and E.N.T. examination revealed nothing abnormal. An injection of novocain into the supraorbital nerve relieves the pain for one or two days. What treatment is suggested?*

A.—Supraorbital neuralgia is a term used to describe more than one condition. It may mean a pain strictly confined to the distribution of the supraorbital nerve or it may include any pain situated above the orbit. Supraorbital neuralgia in the former sense is likely to be associated with some tenderness of the supraorbital nerve, and often with hyperaesthesia and hyperalgesia of the skin which it supplies. It is due to a toxic or inflammatory lesion of the nerve itself, and is likely to be relieved temporarily by an injection of novocain into the nerve, and permanently by following this with a few minims of 90% alcohol.

Supraorbital neuralgia in the more general sense may be a symptom of a large variety of disorders. The pain may be referred to this region from the eye, nasal sinuses, and the upper incisor teeth. One form of supraorbital neuralgia is associated with migraine and is known as migrainous neuralgia. Trigeminal neuralgia usually involves the ophthalmic division only after the second or third division is already affected. Lastly, it must be remembered that such pain is sometimes psychogenic. The treatment will depend upon the cause.

Autogenous Vaccines in Tuberculosis

Q.—*A male patient aged 35 had pulmonary tuberculosis, confirmed by x-ray examination and positive sputum. Before the war he was given an autogenous vaccine, and has since kept perfectly fit. Is this case exceptional, and is there any risk in giving a patient with a positive sputum an autogenous vaccine?*

A.—It is unlikely that the administration of an autogenous vaccine was instrumental in causing the apparent recovery of this patient Spontaneous "cure" is not an uncommon occurrence in tuberculosis, and it accounts for the occasional apparent successes of popular nostrums. It is possible that the patient's symptoms were due to secondary infection of an indolent fibrocavernous lesion and that the vaccine helped to control this secondary infection. Autogenous vaccines have been recommended for the treatment of cases of this type, but few authorities are convinced of their value

Effects of Putrefied Meat

Q.—*May I continue the discussion on putrefaction of meat, poultry, and game (*JOURNAL, *Oct. 20, p. 555). The wild Naga tribes of N.E. India appear to prefer their meat putrid. I was inclined to think this was a case of acquired immunity. On the other hand, I have seen cases of nausea, vomiting, and diarrhoea—usually transient—in ordinary individuals who have eaten partly putrid venison. However, I have never seen similar ill effects from eating game, such as grouse, partridge, etc., in this country or abroad Have experiments been carried out to ascertain the effect of "extracts" made from putrid game on cultures of some of the ordinary pathogenic organisms?*

A.—Your correspondent's experience of putrid meat being eaten by Naga tribes without harm is quite in line with experience elsewhere. His other remark, that transient symptoms may occur from the consumption of such foods in individuals, is less well authenticated, but "high" venison might be contaminated with pathogenic staphylococci and so might contain toxic enterotoxin. He asks if experiments have been carried out, and the answer is, Yes. Savage (*J. Hyg.*, Camb., 1921, **20**, 69) carried out a long series of experiments with kittens (the most suitable animal), feeding them daily for at least a week with meat foods in an extreme state of decomposition. The general result was that, apart from some loss in weight in some of the kittens, there were no symptoms or detrimental effects. Savage remarks: "In no case was there the slightest evidence of infection or any ill effects, apart from disturbances of nutrition, probably to be accounted for by the nauseating food." The experiments also included feeding with large quantities of the bacteria isolated from these highly decomposed foods, and with sterile filtrates. Decomposed fish was used as well as decomposed meat. Considering the whole question, including a study of a very large number of food-poisoning outbreaks, Savage adds that his investigation "singularly fails to bring forward any evidence associating the consumption of food in a state of incipient putrefaction with illness in those who consume it."

Dry Rot

Q.—*What is "dry rot"? Is it caused by a fungus? What steps can be taken to prevent its spread? Is there anything in the superstition that dry rot in a house is detrimental to the health of its occupants?*

A.—Dry rot is caused by a fungus, *Merulius lacrymans* Fries Timber which is attacked is reduced to a dry, powdery consistency; hence the name of the disease. Occurrence of the fungus is always associated with excess of moisture in the timber. Common predisposing causes are the use of unseasoned wood, leaky pipes, faulty gutters, inadequate dampcourses, and cracked or porous walls. Trouble may also arise from lack of ventilation and consequent accumulation of very humid air. Once established, *Merulius lacrymans* spreads rapidly and is capable of forcing its way through brick or stone walls in search of fresh food. Prevention of spread involves: (1) finding and removing the source of moisture; (2) complete removal of all infected wood; (3) replacement with well-seasoned timber treated, preferably by pressure impregnation, with creosote or copper naphthenate.

The only way in which dry rot in a house may affect the health of the occupants is by the sudden collapse of floors or other structural timber. The superstition probably arises from the fact that the damp conditions which favour growth of the fungi may, in themselves, affect health adversely.

Demerara v. White Sugar

Q.—*How does sugar-cane or beet become the white product on our table? Are any vitamins or minerals lost in the process? Is demerara sugar better than white sugar?*

A.—The juice obtained from beet-root or cane is evaporated and sugar crystallizes out. This sugar is redissolved and purified by the precipitation of salts, such as calcium carbonate, in the solution, and by treatment with activated charcoal. Vitamins and minerals of the cane or root are lost in the process. In the case of beet-root the chief vitamin lost is ascorbic acid.

Demerara sugar contains small amounts of nitrogenous impurity, calcium, and iron, which are almost completely absent from white sugar. If our present ration of sugar were taken as demerara sugar it would increase the day's calcium and iron by 17 mg. and 0.3 mg. only.

INCOME TAX

Expenses of Employment

W. T. inquires what expenses are allowable to a whole-time M.O.H. for income-tax purposes.

⁂ The statutory rule is that expenses wholly, exclusively, and necessarily incurred in the performance of the duties of the employment are allowable. This covers the cost of running a motor-car in so far as it is used for the purposes of the employment and the cost is not met by the employer. "Capital" costs—e.g., the cost of purchasing a car—cannot be deducted, but a depreciation allowance can be claimed annually. Subscriptions to professional societies can be deducted if the employer requires the employee to belong to the societies in question.

LETTERS, NOTES, ETC.

Examination Questions for Radiographers

Dr. HUGH MORRIS (Manchester) writes: Can anyone connected with the Society of Radiographers tell a mere radiologist what importance is attached in radiographic circles to the lymphatic drainage of the breast? For, believe it or not, candidates for Part I of that society's November examination were expected to be able to describe that drainage in detail. Surely the examiners can find, in the whole of the human body, enough questions bearing on the daily work of the radiographer without hunting for questions that are not of the slightest practical importance. Or is it that they have been reading some of the questions for the S.R.N. examinations and have decided to produce semi-medical radiographers? Whatever it is, it should never have happened.

Phytic Acid and Calcium Deficiency

Dr. J. P. McGOWAN (Aberdeen) writes: Regarding your annotation on phytic acid and calcium deficiency (Nov. 3, p. 610) may I point out again that rickets is due not to a lack of calcium but to a lack of phosphate. The simple fact that vitamin D is useless in preventing or curing the condition due to calcium deficiency (osteoporosis) ought to leave no doubt that this condition is not rickets.

Ichthyosis

"A DOCTOR'S WIFE" writes: I have just read the question and answer headed "Ichthyosis" (Nov. 17, p. 713). It occurred to me that it might be of interest to give my experience of treating this condition in my own case (even though I am a laywoman).

My father—now aged 85—has always had marked ichthyosis. Loose flaking scales up to 3/4 in. in diameter are quite usual, particularly on his legs and arms. As a child the skin all over my body—and to a lesser degree on my face—was very dry and scaly; and a source of great misery and shame to me, particularly when staying in other people's houses, where I left a trail of skin at each dressing and undressing. It improved very slightly about puberty. When about 17 I discovered the advantage of using some cosmetic cream on my face and hands after each washing. Later I began experimenting with the rest of my body, and after some years, during which I tried a great many different things, I finally found that I could keep the condition almost completely in check by a daily hot bath with superfatted soap, followed immediately—and this is most important—while the skin is still slightly moist and warm, by a fairly liberal application of paraffin. molle alb. While the skin in still moist and pliable this is almost immediately absorbed, but sometimes a slight excess has to be wiped away before dressing. I found that by regularly doing this, and also exposing the skin gradually to the sun and air after sea-bathing (followed, of course, by an application of the ointment) during every spell of fine weather, my skin is, in the summer, able to sweat and tans well, while becoming almost as smooth as the average skin. In the winter, although drier, it does not scale or crack.

As this skin disorder can be a source of great misery, particularly to women, I have felt it might be helpful to give the result of my many years of experiment. This is not of course a cure, and it relapses to its former state if for any reason I have to miss my routine treatment. One other thing: in my experience liquid paraffin is not nearly so good—it is not well absorbed and aesthetically is unpleasant, leaving the skin shiny and soiling the clothes. Also yellow petroleum jelly is irritating over a long period, is not so emollient, and not well absorbed. No ointment, I find, is the slightest use unless the skin has been warmed and wet before rubbing it in.

Surgical Emergencies in Dogs

Dr. FARQUHAR MURRAY (Newcastle-upon-Tyne) writes: I have had two black Aberdeen terriers. Both had major surgical emergencies and made excellent recoveries. *Case 1.*—At 8 weeks old it hurriedly gulped the knuckle of a chop bone, which became impacted between the glottis and the sternum. It was diagnosed by Mr. Elphick (veterinary surgeon) and confirmed by *x*-ray examination. The bone showed clearly in the photo like an arrow-head with the prongs upwards. Under nembutal the oesophagus was opened and the bone, which had been impacted for four days, removed. The dog was back in my house, with the stitches out and the wound completely healed, in three days. *Case 2.*—At 2 years old it suddenly flopped one morning, and during the day showed symptoms suggestive of obstruction. It retched repeatedly and made abortive efforts at defaecation. Mr. Colin Welsh (veterinary surgeon) considered there was intestinal obstruction, but neither *x*-ray nor palpation nor repeated rectal examination was able to determine the site or the cause. A later rectal examination showed blood and mucus, and he diagnosed an intussusception. He operated under nembutal at 2 a.m. next day, and found a gangrenous ileo-colic intussusception with local peritonitis. He resected the mass and did a lateral anastomosis. The dog was back in my house, with the stitches out and the wound well healed and as fit as a fiddle, in six days. I mention these two cases not only for their surgical interest but also in the firm belief that possibly in the secretions of dogs we may find something comparable to penicillin. I quote them also out of admiration for members of an allied profession whose diagnostic ability and technical skill are well worthy of recognition.

A Question of Nationality

Dr. J. UNGAR writes: In his lecture, reproduced in the *Journal* of Nov. 10, Sir Howard W. Florey mentioned the pyocyaneus protein used in the treatment of varicose ulcers by Honl and Bukovsky, who are described as Russians. The two above-named investigators were actually Czech professors at the Charles University in Prague, and their original work was published in the Slav language in the *Proceedings* of the Royal Academy of Science and Art some forty years ago, and therefore hardly accessible now. The information Sir H. W. Florey got was from abstracts in German journals, and that is why the origin of the two was erroneously attributed to another Slav nation.

Journals and Books for Italy

Major W. MACKENZIE, R.A.M.C., wishes to thank the many doctors who have contributed whole-heartedly in response to his appeal (July 7) for British medical publications, of which there is still a need in Italy. Parcels should in future be addressed to Lieut.-Col. G. Frizelle, R.A.M.C., Deputy Director, Public Health Subcommission, Allied Commission Headquarters, Rome.

Corrections

Dr. J. L. BURN, M.O.H. for Salford, writes to point out an error in the annotation entitled "The Case for Nurseries" published on Nov. 24 (p. 735). The letter printed in the appendix to the memorandum was not from the medical officer of health for Salford, but the medical officer of health for Smethwick. Dr. Burn does not agree with the statement that the dangers described "are entirely theoretical." Although these dangers may have been over-estimated in the past they are, he says, real and demand great vigilance and effort.

The report of Dr. Wenyon's presidential address which appeared in last week's issue contained a mistake in the account of Lieut.-Col. W. H. Hargreaves's work on amoebic dysentery and the importance of eradicating bacterial infection by penicillin or one of the sulphonamides in the treatment of resistant cases (p. 775). Col. Hargreaves's name was inadvertently written Henderson.

BRITISH MEDICAL JOURNAL

LONDON SATURDAY DECEMBER 15 1945

THE PROPOSED NATIONAL HEALTH SERVICE

FUNDAMENTAL PRINCIPLES OF THE MEDICAL PROFESSION

The principles set out below were drawn up and agreed upon last week by the Negotiating Committee. This committee is composed of representatives of the British Medical Association, the Royal College of Physicians of London, the Royal College of Surgeons of England, the Royal College of Obstetricians and Gynaecologists, the Royal Scottish Medical Corporations, the Society of Medical Officers of Health, and the Medical Women's Federation. The Negotiating Committee is therefore truly representative of the medical profession and speaks on behalf of all medical men and women in this country.

All Government proposals for a National Health Service should be looked upon in terms of these principles, and when the principles are infringed in any one particular the medical profession should be able to unite itself in opposition. So long as none of these principles is infringed then the profession should find no difficulty in co-operating with the Government in working out the administration of a National Health Service.

For a quarter of a century the medical profession has stressed the need for a complete health service.

The profession is willing and anxious to co-operate with the Government in evolving this service, for it believes that the knowledge and experience of the profession are indispensable contributions to its success.

It re-emphasizes that good housing and social, economic, and environmental circumstances are the principal factors in the maintenance of health and the prevention of disease. It urges the expansion of medical research.

In the interests both of the public and of medicine the profession regards the acceptance of the following principles as essential:

I. The medical profession is, in the public interest, opposed to any form of service which leads directly or indirectly to the profession as a whole becoming full-time salaried servants of the State or local authorities.

II. The medical profession should remain free to exercise the art and science of medicine according to its traditions, standards, and knowledge, the individual doctor retaining full responsibility for the care of the patient, and freedom of judgment, action, speech, and publication, without interference in his professional work.

III. The citizen should be free to choose or change his or her family doctor, to choose, in consultation with his family doctor, the hospital at which he should be treated, and free to decide whether he avails himself of the public service or obtains independently the medical service he needs.

IV. Doctors should, like other workers, be free to choose the form, place, and type of work they prefer without Governmental or other direction.

V. Every registered medical practitioner should be entitled as a right to participate in the public service.

VI. The hospital service should be planned over natural hospital areas centred on universities in order that these centres of education and research may influence the whole service.

VII. There should be adequate representation of the medical profession on all administrative bodies associated with the new service in order that doctors may make their contribution to the efficiency of the service.

STATEMENT BY MINISTER OF HEALTH

COMPENSATION IN RESPECT OF MEDICAL PRACTICES

The following statement was made by the Minister of Health in the House of Commons on Thursday, December 6, 1945:

"The Government have not yet finally decided upon the proposals which they will be submitting to Parliament for a National Health Service.

"They believe, however, that it will be incompatible with the provision of an efficient service that the future exchange of medical practices and the creation of new practices within that service should be left entirely unregulated and that no effective steps should be taken to secure a proper distribution of doctors to fit the public need.

"I appreciate that intervention in this field, in whatever form it may take, will probably have the effect of preventing the sale and purchase of the practices of doctors taking part in the new service, and the Government therefore think it right to give warning of this probability at once and in advance of the formulation of their full proposals.

"At the same time and in order to allay the natural anxieties of doctors already in practice, or coming into practice from the Forces or elsewhere, the Government wish to make it clear that there will be an appropriate measure of compensation to doctors in respect of loss of capital values directly caused by the new arrangements.

"It is intended that discussion should be undertaken immediately with the profession's representatives with regard to the steps to be taken to give effect to this decision."

STATEMENT BY SECRETARY OF NEGOTIATING COMMITTEE

The Secretary of the Negotiating Committee of the medical profession, Dr. Charles Hill, made the following comment on the Government statement:

The Government's undertaking to pay compensation for any loss of capital values incurred by doctors as a result of its new proposals—whatever they may turn out to be—is plain justice. The capital represented by a doctor's practice is something which he has paid for or built up and something which he relies upon for his retirement years. Any Government which takes steps to destroy or diminish a capital asset should compensate for the loss it causes, and this Government's desire to relieve anxiety on this point of principle is appreciated.

When a practice changes hands what is in fact transferred is goodwill, the patients themselves being free to accept the incoming doctor or choose another doctor as they please. Many will not share the Government's view that an efficient medical service can be secured *only* by such a fundamental change in existing arrangements. This has yet to be argued. The Negotiating Committee representing the medical profession has not yet had an opportunity of putting forward to this Government its own proposals for a complete health service, including those for a wider distribution of doctors.

The abolition of goodwill cannot be considered in isolation. What matters most is what machinery the Government proposes to substitute for the present arrangements in order to facilitate the entrance of doctors into medical practice and their freedom of movement thereafter. If, for example, it is proposed to substitute for existing arrangements a system of *posting* or *direction,* the medical profession will be opposed to it. If the Government assumes that by destroying the goodwill of existing practices it thereafter becomes entitled to appoint doctors to practices, directing them where and how and with what colleagues they shall practise, the proposal is fraught with danger to public and professional freedom. Doctors should, like other workers, be free to choose the form, place, and type of work they prefer without Governmental or other direction.

For these reasons the attitude of the medical profession to any proposal to abolish the sale and purchase of practices can be determined only when it is known what is to be substituted for the existing arrangements. To promise compensation if capital values are affected by the new arrangement is only fair and just. But whether it is necessary to introduce such new arrangements, and whether such arrangements involve the loss of the essential freedoms of the public and the profession, can be judged only when all the cards are on the table.

LIVERPOOL SCHOOL OF TROPICAL MEDICINE

The forty-sixth report of the Liverpool School of Tropical Medicine states that Lieut.-Col. B. G. Maegraith, who was recently appointed to the Alfred Jones Chair of Tropical Medicine at the University, in succession to the late Prof. Warrington Yorke, has taken up his duties in the School, and has brought with him Surg. Lieut. R. E. Havard, whose services have been lent by the Royal Navy for the purpose of continuing in Liverpool the work on the therapy and pharmacology of mepacrine which had been carried on in the Army Malaria Research Unit under Prof. Maegraith's direction. Clinical trials of new antimalarial drugs synthesized by Imperial Chemical Industries are proceeding and the pharmacology of the most promising of them is being investigated in human volunteers and in patients. It is stated that the preliminary investigation of one drug of great promise—it is unnamed in the report, but apparently it is paludrine—is now being carried out both in prophylaxis and treatment in the field of the South-West Pacific and in India. Prof. Maegraith has undertaken a full investigation into its pharmacological properties, and the report adds: "There is reason to hope that this new compound may play an important part in the future treatment of malaria and that its development may lead to the preparation of further compounds even more effective."

The first investigation in this country of penicillin as a remedy for syphilis was entrusted to the Department of Chemotherapy at the School by the Penicillin Clinical Trials Committee of the Medical Research Council. This work is being undertaken in conjunction with the laboratories of the Public Health Department of the Liverpool Corporation. A serious limitation to the large-scale use of penicillin in a campaign against syphilis in civilian communities is the necessity, in officially recommended schemes of treatment, for confining patients to hospital during the course of injections. One of the main objectives of the present investigation, under Dr. E. M. Lourie, has therefore been to establish forms of penicillin treatment which would be effective if administered on an out-patient basis, without requiring any interference with the patient's daily occupation. Considerable progress has been made towards this end, and a report is in an advanced stage of preparation. Many data have also been accumulated on the fate of penicillin in the body, after injection and on the mechanism of its action against spirochaetes.

SURVEY OF FRACTURE TREATMENT*

BY

C. MAX PAGE, C.B., D.S.O., F.R.C.S.

The survey which I propose may be aptly introduced by a consideration of the historical side of the matter. Precise separation of the history of any subject into periods, convenient though it may be, is never fully accurate: any one period is in some degree the child of the past and the parent of the future. Acknowledging this limitation, I will divide the development of fracture and dislocation treatment in an arbitrary manner into three sections. The first may be called the "Galenical," extending from the earliest historical period to the Renaissance; the second, the "Hunterian," which follows it and reaches the time of Lister; and, lastly, the "modern," which within this century has been determined by the full development of aseptic surgery and radiological technique.

The Galenical Period

The treatment of fractures and dislocations, if perhaps the simplest, is also the oldest section of the surgeon's art. Material for its study has been available in quantity so soon as a definite social organization was established. As early as the second millennium B.C., the reputed date of the fragmentary Edwin Smith papyrus (Breasted, 1923; Hussein, 1934), precise instructions on the management of some fractures and dislocations are to be found; in the Hippocratic canon of about 600 B.C. a more extensive account of the subject is set out. The Egyptian document reveals a remarkably high level of practice in some branches of surgical knowledge: for example, the treatment prescribed for a grossly displaced fracture of the clavicle closely resembles the procedure advised to-day in some textbooks for the management of a similar injury in the case of a society beauty; the description of the diagnosis and treatment of a dislocated jaw might usefully inform the modern casualty dresser. In the Hippocratic treatise there is a fairly full account of the treatment of fractures and dislocations. The methods advised remained the basis of treatment up to and including the time of Ambroise Paré. For the rest of the Galenical period the lack of further literary evidence on current technique of fracture treatment is, however, striking: though it is true that in the first renaissance of French surgery in the early 14th century Henri de Mondeville and Guy de Chauliac did include the subject of fractures in their writings, this section of the former's works has been lost and that of the latter is essentially based on the Hippocratic tradition derived from the Arabian school. The same absence of written accounts of the subject is also noticeable in medical treatises of the early Sumerian, Indian, and Chinese medical writings. We may perhaps deduce from this that fracture management in the periods in question was mainly in the hands of illiterate practitioners of inferior status to the physician and that knowledge of the subject was passed on by mouth and example only. There is, at any rate, clear evidence that such was the case in the Roman Army organization. In general it would seem that the Roman surgeons and those of the Middle Ages did not get beyond the methods, still valid to-day, of direct clinical observation and the application of simple mechanical devices. This period therefore presents little of value to the active clinician; its interest remains mainly historical or associated with individual drama.

"Hunterian" Period: The Scientific Outlook

It was not till the Renaissance and in what I have classified as the "Hunterian" period that anatomical study and pathological investigation were gradually brought to bear on our subject. The works of Paré are the first to show something of this spirit. The advances in surgery effected by him (Paré, 1840) were mainly in the field of wound treatment. The section of his writings on fractures does, however, reflect his common-sense judgment on practical details. The chapter on dislocations reproduces in the main the traditional Hippocratic methods. Here is one of his figures showing that traction with the pulley and counter-traction were well understood (Fig. 1).

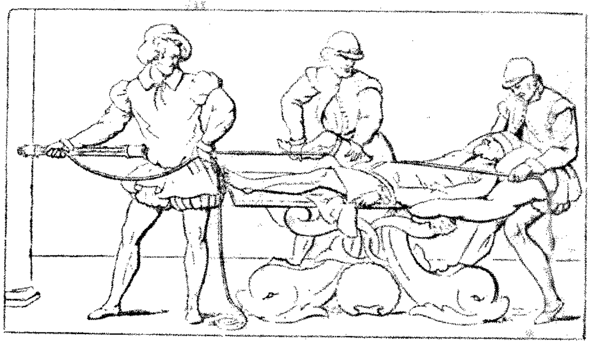

FIG. 1.—Method for reducing an anterior dislocation of the hip-joint. (From Paré's *Surgery*.)

The first contribution made in this country with a scientific outlook on the treatment of fractures was that by Percivall Pott. Pott was undoubtedly, after John Hunter, our outstanding surgeon of the 18th century. His writings range over a wide field, and his monograph on fractures and dislocations was not put forward as a treatise, but was entitled "a few remarks" on the subject and was printed with his *Head Injuries* in 1768 (Pott, 1808). Pott was conscious that all was not well in the treatment of fractures by surgeons of his day, and indeed recalls that he "some years ago had heard a Judge from the bench tell a jury that he believed a country bone-setter knew full as much, if not more, of the matter of his own business than any, the most eminent surgeon in the Kingdom." In his essay on this subject he is concerned to caution against the over-use of traction, and he emphasizes the value of a relaxed position of the joint both in relation to the reduction of deformity and in the maintenance of position after fracture. These principles are exemplified in the treatment set forth in his classical description of fracture-dislocations of the ankle. He appears to have been the first to define the necessity for fixing the joints immediately above and below a fractured long bone. In the treatment of compound fractures he is insistent on the importance of excluding air and advocates the use of a closed dressing, he himself having been successfully treated for an injury of this kind on that principle.

Sir James Earl in editing Pott's surgical work (1808) adds several practical points and gives details of a bed and beam convenient for managing fractures of the femur. This apparatus (Fig. 2) clearly antedates the Balkan beam, which was discovered anew in 1912.

---

* Bradshaw Lecture before the Royal College of Surgeons of England on Nov. 8, 1945 (abridged).

Sir Astley Cooper first published his more ambitious treatise on the subject in 1810 (Cooper, 1823). The work is based on clinical lectures and case reports, and contains some fine plates (Figs. 3 and 4). His practice shows no great advance in detail on that of his predecessor. He extolled the value of the inclined plane (introduced by White of Manchester) for the treatment of fractures of the shaft of the femur. His main claim to fame is based on his study of the intracapsular fracture of the neck of this bone. He clearly differentiated the outlook for intracapsular fractures from that for the extra-articular variety. He analysed the cause of non-union in the former, carrying out some experiments on dogs to prove his views, which closely conform to those held to-day. The ability to establish the differential diagnosis of these injuries without the assistance of radiology is a striking tribute to the clinical acumen of the surgeons of that time—though one cannot think they were always correct. For the treatment of intracapsular injuries he advocated 10 days in bed, after which the patient was placed in a chair and gradually worked up to such weight-bearing as he could manage. This style of treatment was still in vogue when I was a student.

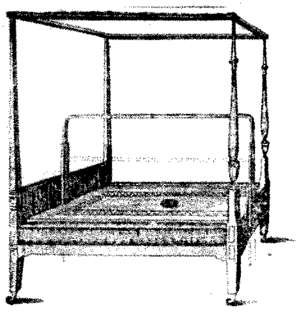

FIG. 2.—Earl's bed and beam.

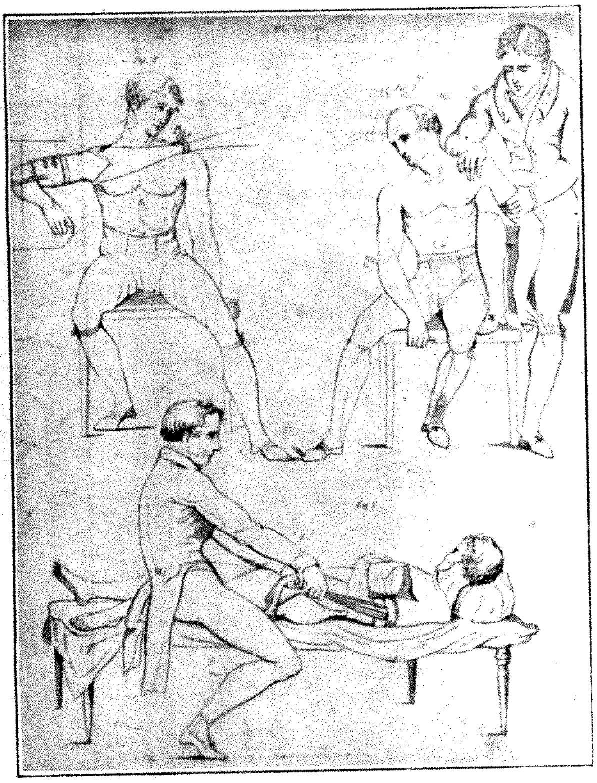

FIG. 3.—Astley Cooper's treatment of dislocation.

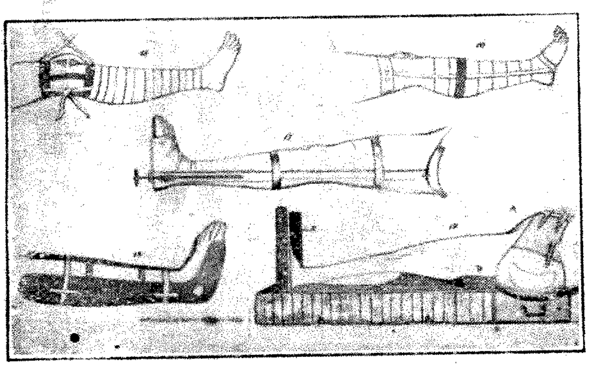

FIG. 4.—Astley Cooper's splints.

Evidence of the somewhat crude standard of surgical methods in the early part of the 19th century, particularly in relation to the reduction of dislocations, is to be found in many case reports reproduced by Malgaigne (1847). He recites the experience of Delpech, who had some difficulty in reducing a dislocation of the shoulder recently sustained by the Mayor of Nîmes. Traction was exercised by 10 assistants and is said to have been successful in obtaining reduction, but during the manipulation the Mayor turned pale, lost consciousness, and did not recover—he was found to be dead.

Michaux, at Louvain, when attempting to reduce a recently dislocated elbow in a boy of 10 produced a rupture of the brachial artery. Gangrene followed, and the arm was amputated six days later. Flaubert, the well-known Rouen surgeon and father of the author of *Madame Bovary*, reports on a woman of 70 with a 38-day-old axillary dislocation of the humerus. Eight assistants were charged with applying traction. The cries of the patient were so violent that emphysema was produced below the clavicle. This was followed by a hemiplegia and syncope. Death took place 18 days later. A dissection showed that the four lower cords of the brachial plexus had been torn out of the cord. Altogether Malgaigne reports 11 ruptures of the axillary vessels, 3 examples of avulsion of the brachial plexus, and one of ruptured lung from similar procedures, all being conducted without anaesthesia. He himself advises that when traction and manipulation have been carried on for half an hour without success it is prudent to stop.

During the latter part of the "Hunterian" period the literature shows a great development of interest by the general surgeon in fracture treatment. Most of their contributions were concerned with methods of splintage and bandaging, and it may be well to consider here this section of our subject. From an early period padded wooden splints were in common use; the splints were plain slats of wood, and a fit to the contour of the limb depended on the padding. In Egypt in the dynastic period sewn bundles of reed were employed, and were of a more adaptable nature. Similar appliances of straw or reed—called farrons—were also well known and in use by most surgeons in the Middle Ages. Bandages of linen or other woven material date back to the earliest times. The introduction of bandages impregnated with egg-white and flour is attributed to Albucasis in the 11th century, and their use is mentioned by Paré, Fabricius, Wiseman, Cheselden, and Larrey, and they had considerable popularity till displaced first by the starch bandage of Seutin and later by those impregnated with plaster-of-Paris (Malgaigne, 1840). The use of the latter is now so fully established and forms so important a part of the fracture surgeon's equipment that it is of some interest to trace its gradual development.

Development of Use of Plaster-of-Paris

Oddly enough, the earliest application of plaster-of-Paris is attributed to the surgeons of the Middle East. In 1760 a Mr. Eaton, English Consul at Basra, reports an instance of broken leg treated in plaster with success by a native practitioner after amputation had been advised by a European surgeon. Malgaigne states that plaster-of-Paris was first used in Europe in 1814 at Groningen, and a few years later by Hubenthal. The practice of the latter was to oil the skin and use two half-moulds bandaged together. In 1828 Keyl in some degree popularized the method at the Charité Hospital in Berlin. In English literature the earliest published references came from provincial centres. Bond and Gale (1833–4) of Glastonbury recorded the use of a plaster mould in the treatment of a fracture of the femur. They associated traction applied through an anklet, and say that this was the only source of trouble in the management of the case. These authors further suggest the use of the method for fractures of the neck of the femur, and say that for such injuries both femoral trochanters should be enclosed in the plaster.

In the same year Dr. Browne (1833–4) of Drogheda reported in the *Lancet* that a medical gentleman, middle-aged but of active habits and sanguine temperament, fell from his horse on a rough road and sustained a fracture of the tibia about its centre. At the end of six weeks there was no union, and so the author and a colleague proposed to pass a seton between the fragments: this the patient refused, and Prof. Kirby of Dublin was called in consultation. He put the leg in a complete plaster mould—" the leg, foot, and lower quarter of the thigh were encased in plaster-of-Paris 1 in. to 1½ in. in thickness." Union was found to have taken place six weeks later.

Dr. Browne says Prof. Kirby had used the method for fractures of the legs for 10 years past. The only criticism advanced by the former was the need for hard work with chisel and hammer in order to remove the case in due course.

It is sometimes stated that plaster-of-Paris was employed by Larrey during the Napoleonic campaigns, but I can find no record of this. The idea may have arisen from Larrey's strong advocacy of " appareils immobiles " (Larrey, 1812). These were constructed with the help of bandages impregnated with flour and white of egg. He records leaving such applications on compound fractures and amputation stumps for several weeks or even months without re-dressing, and with very great success. His advocacy of the closed dressing seems to have been but little followed till the time of Unna, Winnett Orr, and Trueta.

The plaster bandage was undoubtedly invented by a Dutch Army surgeon Mathijsen (1852). The value of this technique in fracture treatment was fully recognized, and publicized, by a Belgian, Van de Loo (1852–3). The method attracted great interest at the time in the Belgian Academy of Medicine and was discussed there with considerable acrimony; it was finally submitted to a Commission of the Academy in 1852 for report. A majority verdict in favour of the procedure was returned.

Plaster splintage was employed by both French and Germans in the war of 1870 (Délorme, 1888–93), and its use in the Crimean War is reported on by Pirogoff (1864), but I have not been able to find details of the exact methods employed. In England the application of plaster found little support till Croft (1878) of St. Thomas's published his method of making a bivalved case from impregnated house flannel. Maisonneuve had at an earlier date, in France, introduced the use of plaster-soaked tarlatan strips—a technique which was subsequently employed and elaborated by Delbet (Le Dentu and Delbet, 1915) in his ambulatory splints. The later history of the use of plaster-of-Paris takes us forward to recent times.

Before turning to the " modern " period I would call attention to a point of interest: the publications of British surgeons on fracture treatment during the 19th century and the first decade of the present century are singularly lacking in number or interest, though the monograph of H. O. Thomas, published in 1886, and that of Lane, which appeared in 1905, form exceptions to this statement.

To judge by its literature the surgery of injuries attracted considerable attention in France and Germany during the same period. Malgaigne stands out in the first half on account of both his bibliographic industry and his scientific approach to practical problems. Bardenheuer elaborated a system of the positional treatment of all fractures by means of traction applied with the help of adhesive strapping, following Buck. His monograph (Bardenheuer, 1889) represents a definite advance in the mechanical conception of the subject, the principles of which form the basis of most methods in use to-day. Helferich (1895) of Munich produced the best textbook on fractures in the latter half of the century, and in his later editions he describes and figures Thomas's knee-splint in relation to the treatment of the fractured femur and extols its use for ambulatory purposes three or four weeks after the injury. Jonathan Hutchinson junior abstracted this work for the New Sydenham Society in 1897 and reproduces these particulars. In the U.S.A. full textbooks on the subject were published by Stimson and Scudder towards the end of the century.

The " Modern " Period

The " modern " period is introduced by the discoveries of Pasteur, and their application by Lister to surgical technique. The value of antisepsis in the treatment of compound fractures was soon generally, though by no means universally, recognized, and the operative treatment of a limited group of fractures had been carried out sporadically since Lister had shown the possibility of wiring the patella with impunity. Lane in this country, and contemporaneously Lambotte of Antwerp, were the first to employ the method systematically. Lane published his *Operative Treatment of Fractures* in 1905 and Lambotte in 1906 (Lambotte, 1913). Both authors produced second editions of these monographs. It must be admitted that the French work, in its study of the mechanical side of the problem, is much the superior. Lane devoted a large part of his book to a disquisition on body position and function in relation to advanced osteo-arthritis. He displayed a superb self-confidence in his own methods and a considerable contempt for the abilities of his contemporaries. His exposition of the " no-touch " technique was perhaps the most valuable part of the publication. Here is the introductory paragraph to his description of it.

> " If the surgeon has not succeeded in such a simple operation as wiring fractures of the patella without killing or permanently disabling many of his patients, he had better bring himself to believe that the results of the generally accepted methods of treatment are excellent, and that any statements to the contrary are exaggerated or imaginary, and leave operations on recent fractures alone, since they may test the methods and skill of the operator to the utmost."

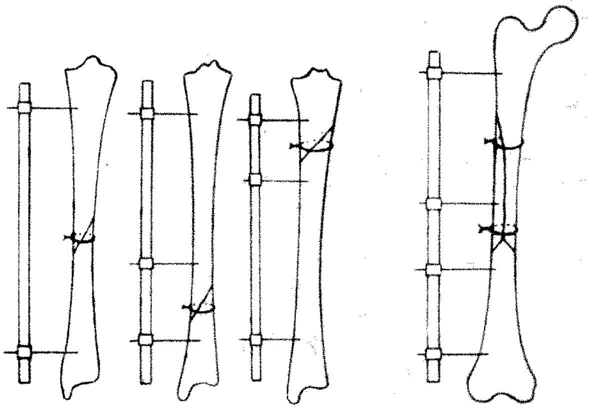

Fig. 5.—Diagrams showing Lambotte's " prothèse externe " method. (From *Chirurgie Opératoire des Fractures*, 1913, Paris.)

Lambotte discusses in detail the relative merits of various interior fixing agents. He designed plates shaped to the contour of the bone-shaft and employed screws with a grub (Whitworth) thread. He appreciated the value of transfixing with his screws both sides of the bone when operating on diaphysial injuries. He also introduced his " prothèse externe," the origins of which he traces to Malgaigne's hooks and suggestions of Rigaud; he was of the opinion that it was the ideal method for managing fractures of the shaft of the thigh and tibia (Figs. 5 and 6). Its failure to gain acceptance was presumably due to the frequency with which infection arose round the rod-holes.

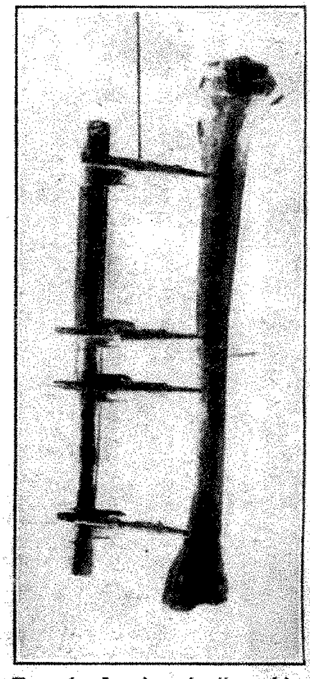

Fig. 6.—Lambotte's " prothèse externe." (From *Chirurgie Opératoire des Fractures.*)

Osteosynthesis by screw and plate, however, gained a considerable hold on the surgical world. Sherman in Cleveland championed it in America, and it has held its place in France up to the present time. In this country its many failures in other hands than those of Lane were instrumental in preventing its routine adoption and in creating some prejudice against it.

Another school of fracture treatment which came into being in the same period was that of Lucas-Championnière. In 1880 he published his *Le Mouvement est la Vie*, and in 1895 the bulky *Le Traitement des Fractures par le Massage et la Mobilisation.* His views were much criticized by surgeons of the day, and his method found little place in the treatment of injuries of the lower limbs. Its value in upper-limb fractures was considerable, and in 1912 Dr. J. B. Mennell organized a successful out-patient fracture clinic at St. Thomas's Hospital which followed this school. Moreover, its general influence was important in turning surgical thought towards the maintenance and restoration of function of the soft parts after injury.

In 1907 Steinmann (Steinmann, 1907, 1912) put forward his "Nagelextension"—a system based on Bardenheuer's application of traction, but with a direct nail- or pin-hold of the bone in place of adhesive plaster. He had been preceded by Codivilla so far as the basic idea was concerned. Despite the full exposition of his method in the German press it attracted no attention in this country till 8 or 10 years had passed.

It is about this date that the outstanding influence of the advance in radiology comes into evidence. The precision in the diagnosis of fractures which it furnishes has had its repercussions. The patient may expect too much from his surgeon; the surgeon may be over-impressed with the importance of complete reduction of displaced fragments. Another contribution, however, is the recognition of fractures where none were recognized before. Linear fractures of the carpal scaphoid and the various stress fractures are examples of this. Whether the elaboration of treatment imposed by such recognition has always been in the interest of the patient is a matter of opinion. In another direction advance in radiological technique has been equally interesting: the process of bone absorption and formation can now be almost kept under view, and this evidence forms the basis on which a new pathology of bone may be built up. If we do not all agree on, or if we are ignorant of, the why, we are able to observe the changes which bone undergoes both at the seat of injury and at a distance. The post-traumatic dystrophies of bone and the problems of calcium metabolism await the future for their elucidation.

Wartime Stimulus to Fracture Treatment

The advent of war in 1914 exposed the poverty in knowledge of fracture treatment of British surgeons as a whole. Initially, the Army splint equipment was antiquated and insufficient in quantity for the scale of casualties met with. The long Liston was the only splint available for fixing the broken thigh in the field or at the base. We had no idea of the value of the Thomas splint in the management of a broken thigh; the same was true in regard to the use of skeletal traction. Sir Robert Jones, with promptitude and great activity, made known the use and induced the production of the former. This introduction of the Thomas splint was of major importance in reducing loss of life or limb after open fracture of the femur. Its advent was enthusiastically acclaimed by Army surgeons, and incited the introduction of many auxiliary gadgets and modifications in its form and methods of use, some of which still make the Liverpool purist rend his hair. The application of skeletal traction was more slowly adopted. It was first employed in the not very satisfactory form of a calliper. Plaster-of-Paris was seldom used by us in the field during the campaign, though both German and French Armies employed it at that level.

The stimulus given to the study of injury treatment during four years of war was passed on to the peaceful years. Monographs and contributions on fractures and their treatment became so numerous for the next 20 years that I shall not attempt to analyse them all. Indeed, I may quote Shakespeare:

> "Vouchsafe to those who have not read the story,
> That I may prompt them: and of such as have,
> I humbly pray them to admit the excuse
> Of time, of numbers and due course of things."

Certain trends of thought and some individual techniques may well be studied. The 1914 war had shown the value of segregation of certain injuries in its reaction both on the individual patient and on progress in methods of treatment. The Delevingne report showed how much segregation would benefit the general population in peacetime. A fracture clinic had been organized at the Ancoats Hospital at Manchester immediately after the last war by Harry Platt (1938) and formed a model which has extended to most other large hospital centres. I will not attempt to decide whether such organizations should limit their activities to the treatment of fractures only, or whether they should include certain other injuries or accidents in general. Nor will I discuss whether such services should be directed by a general or a so-called orthopaedic surgeon. I think their undoubted success in fracture work has been based on the provision and training of whole-time assistants skilled in splint management and plaster work. The control of their own *x*-ray apparatus, the arrangements for routine after-care, and the central management of rehabilitation are further advantages possessed by units of this character.

Skeletal traction, as has been mentioned before, came into use among British surgeons at the end of the 1914 war. The introduction by Kirschner in 1927 of strained wire in the place of nails or pins gave an impetus to its popularity and an opportunity for the invention of much ingenious auxiliary apparatus (Wilson, 1932). I am inclined to think its application to hand and foot fractures did more harm than good; its use for the major bones seems to be declining in popularity as opposed to the rigid pin. The power of skeletal traction can be such that distraction of the broken ends of the bones is easily effected. There is a widely held impression that operation of this factor has been responsible in the latter years for a considerable increase in the incidence of delayed union or non-union.

The school of Boehler in Vienna made a considerable impact in this country in the early 'thirties (Boehler, 1935). His association of the skin-tight plaster with active movement may be said to have embraced both the ideas of Lucas-Championnière and of Delbet without showing the failings of either. His reduction of the deformities in impacted fractures of the os calcis and vertebral bodies opened up new possibilities, which in the case of the latter have proved fruitful in results. I think this influence has been gradually replaced by the Watson-Jones (1943) school working on a wider and more scientific basis. The latter has both introduced new methods and incorporated those which have proved useful in the old.

One of the technical triumphs of the period under consideration has undoubtedly been in the management of transcervical fractures of the femur. Royal Whitman (1925) demonstrated the mechanics of the accurate reduction of these injuries. His method of fixation was the full plaster spica. Despite the success of the method in his hands it possessed many drawbacks, and Smith-Petersen's (1931) introduction of internal fixation by means of a trifin pin overcame many of them. The replacement of closed pinning under radiological control initiated by Johansson (1932) extended the possibility of using the procedure in the feeblest of subjects. The final results have perhaps not come up to our first expectations. Here are some figures collected by Mr. Peter Elmes at Oxford, to whom I am indebted for their use before publication and final analysis; they give perhaps an average picture of the outcome of this method.

Results of Pinning Operations for Transcervical Fractures of the Femur

Cases studied	195
At time of investigation had died	24
" " not traced	43
Too recent to be of value (less than 2 years' follow-up)	13
No. of cases analysed (at least 2-year follow-up)	115
Completely satisfactory	35 (30½%)
Fair results (slight pain or limitation of movement)	42 (36½%)
Failure of union	38 (33%)

No doubt further systematic follow-ups will soon become available, and we may be able to judge how far the failures are due to errors in technique or are inherent in the method. Many active brains are concerned with this problem, and the future should show further improvements in the management of an injury for so long the despair of the profession.

It is perhaps too early to assess the value of the Roger Anderson (1936) apparatus. At first sight this ingenious appliance was so attractive and effective when operated by skilled hands that one felt that the treatment of diaphysial fractures was solved for good. Experience in this country up to date shows that it has drawbacks, and it is well to remember that Lambotte, 30 years ago, thought he had a winner on similar lines.

Deriving perhaps from American and French practice, there has lately been a strong move in some centres to return to the more frequent use of osteosynthesis. The introduction of plates and screws made of metals which develop little or no electrolytic action in the tissues seems to have been one factor responsible, though I incline to the opinion that its importance has been overstressed. The realization of the value of a grub-threaded screw holding both sides of the cortex perhaps carries more weight. What position it will hold in our practice 10 years hence it is difficult to say. If open osteosynthesis is adopted as a routine measure it may be hoped that it will be carried out so as to conform to the ideal set out by Burns and Young (1944)—i.e., to be mechanically sound enough to make post-operative splintage unnecessary and so to allow of activity of muscles and movements of joints at an appropriate time. To carry out an open operation on a broken tibia and fix the fracture with one or two screws, and then encase the limb in plaster for a couple of months, is to concentrate too much on form and to forget function.

The recent war has tested our knowledge and competence in the handling of open fractures, and I think it is generally admitted that British surgery has come well out of the ordeal. No outstanding new methods have been introduced. The Thomas splint, often disguised as a Tobruk, has stood the test of time. The use of the closed plaster, so ably advocated by Trueta, has found its level. The employment of plaster-of-Paris in the field, with due precautions, has been greatly extended, and I think the general use and proper application of the thoraco-brachial spica has saved many arms which would have been lost in the last war.

Conclusion

I must admit that my survey has covered so wide a field that it has been but superficial. I hope it has given some measure of the striking progress which has been achieved in this century. In the immediate future advances in the standard of fracture management will perhaps depend more on the organization of our accident services than on any radical changes in method.

I think I have shown that, in the past, technique has often outridden judgment and experience. I hope that I have demonstrated the importance of controlled observation with any new experiment in this branch of our work.

NUTRITION IN VIENNA IN SEPTEMBER, 1945

BY

MAGNUS PYKE, Ph.D., F.R.I.C.

(From the Nutrition Section, Economic Division, Allied Commission for Austria: British Element)

During the approaching winter Vienna may be subjected to conditions approximating to famine unless strenuous efforts are made by the responsible national elements of the Allied Council. Even under the most favourable circumstances Austria has never produced enough food to support herself, and this year the ravages of war have substantially reduced the amounts normally grown. In order to supply sufficient food for Vienna it will therefore be necessary for provisions to be imported. The physical difficulties of importing supplies are great, and in addition there are competing claims for food elsewhere and the complications of international politics and international finance. It is consequently of interest to study in some detail the present nutritional state of the city in order to be able to gauge with open eyes the probable results of future events as they gradually unfold.

The city of Vienna was captured from the Nazis at the end of April, 1945, after prolonged street fighting. For some time after the fall of the city the local administration was unable to issue weekly rations, and the population were compelled to subsist on any domestic stores of food they might possess. When it became obvious at the beginning of June that domestic and retail stocks were almost exhausted and that the people would starve unless food was provided for them, the Russians permitted the release of sufficient supplies to enable a ration of bread, cereal, meat, fats, and sugar to be distributed. This ration provided normal consumers with about 800 calories daily. Certain types of workers received more, but the biggest ration issued to the heavy-worker category provided only about 1,600 calories. The only official addition to the rations was an issue of a half-litre of milk a day to children up to 1 year old and a quarter-litre of milk to children from 1 to 3 years. No supplement was given to pregnant women. Unofficial additions to the food supply were scanty. For normal individuals no worth-while supplement of calories was available. To obtain vitamin C and vitamin A, in which the rations were entirely deficient, people might acquire small amounts of potatoes and vegetables from gardens or allotments, or they might make expeditions into the country, but, apart from certain supplies for canteens which will be mentioned later, there was no organized provision of fresh vegetables, potatoes, or, except for the youngest children, milk.

Early in September the Allied Council was set up and each of the four nations in the Council assumed the responsibility of contributing food to Vienna. It was jointly agreed to try, as from Sept. 23, to provide the normal consumer with a minimum ration of 1,550 calories (with differentiation: up to 3,000 calories for the very heavy worker; for various other groups, according to the type of labour they perform). Fig. 1 shows the fluctuation in the calorific value of the rations issued to normal consumers in Vienna from Jan., 1945, in the last weeks of the Nazi State, through the period of fighting and disorganization in April and May, when no rations were distributed, up till Oct., 1945, when the Allied Council target of 1,550 calories daily was being achieved.

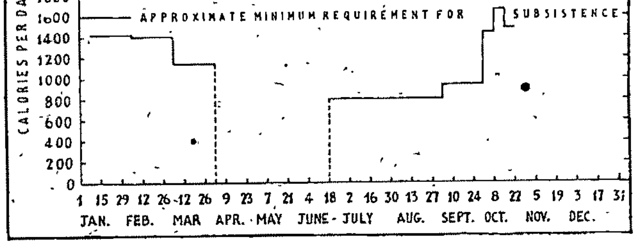

FIG. 1.—Calorific value of the ration for normal consumers in Vienna during 1945.

Dietary Survey

During the second and third weeks of Sept., 1945, an effort was made to assess the composition of the total diet actually being eaten by the population of Vienna. The technique adopted was essentially that used by Wiehl (1942). This method depends upon the questioning of the people about everything they have eaten during the previous 24 hours. Whenever an item is mentioned an equivalent amount made available at the interview is weighed. In the case of soups, which are a distinctive feature of the Vienna diet, and of made-up dishes, plates of different sizes were used to determine quantities. Recipes were obtained from women in a number of districts to discover the amounts of ingredients currently used. The composition of the official rations provided for normal consumers at the time the survey was made is shown in Table I.

makes reasonable provision. The striking difference between the amounts of vitamin A, riboflavin, and vitamin C in the average diets eaten by the two groups of people studied is of considerable interest. If it be assumed that at least 2,500 i.u. of vitamin A, 0.85 mg. of riboflavin, and 25 mg. of vitamin C are required for a subsistence diet it can be seen that, whereas the food eaten by the group in Bezirk III was seriously deficient in all three of these nutrients, in Bezirk XI an adequate intake was available. The reason for these differences appears to lie in the fact that Bezirk XI, which covers the working-class district of Simmering, contains large areas of allotments and is situated nearer the outskirts of the town. Of the people whose diet was studied there, 60% had eaten potatoes during the day and 45% had eaten green vegetables or tomatoes. Some of these potatoes and vegetables were stated to have come from gardens or been brought in from the country; the rest was frankly admitted to have been bought in the black market.

TABLE I.—*Composition of the Normal Consumer's Ration in Vienna during the Week Beginning Sept. 3, 1945*

	Daily Issue (g.)	Calories	Protein (g.)	Fat (g.)	Calcium (mg.)	Iron (mg.)	Vit. A (i.u.)	Vit. B_1 (mg.)	Riboflavin (mg.)	Nicotinic Acid (mg.)	Vit. C (mg.)

TABLE V.—*Composition of the Average Daily Diet Eaten by 10-year-old School-children in Vienna, Sept., 1945*

	Calories	Protein (g.)	Fat (g.)	Calcium (mg.)	Iron (mg.)	Vit. A (i.u.)	Vit. B_1 (mg.)	Riboflavin (mg.)	Nicotinic Acid (mg.)	Vit. C (mg.)
Group of 20 boys	1,340	36	16	360	16	3,250	1·29	0·84	8·6	35
Group of 20 girls	1,250	61	10	260	17	1,660	1·33	0·76	8·2	30

Two groups of normal consumers—that is, people entitled only to the ration shown above—were investigated in different parts of the city. A room was set aside in a public office (Katestelle) in Bezirk III and in Bezirk XI, and people were taken at random for examination from the queues which constantly form in these places. The composition of the average diets eaten by these two groups is shown in Table II. In calculating the nutritional values the table of food composition given in *Nutrition and Relief Work* (1945) has been used in most cases.

It is difficult to assess figures for the minimum nutrient intake needed to maintain an adult at a level of bare subsistence. If 1,600 calories is tentatively chosen as the lowest energy intake capable of preventing continuous physical deterioration, the Vienna diet in September is seen to have been grossly inadequate. Figures of 50 g. protein, 500 mg. calcium, 10 mg. iron, 0.7 mg. vitamin B_1, and 6 mg. nicotinic acid may perhaps be regarded as approximately the daily amounts needed to support subsistence; with respect to these nutrients the diet

Bezirk III, on the other hand, covers a central industrial and commercial section of Vienna. Although 48% of the people interrogated there had eaten some quantity of potatoes, from which the whole of the small and inadequate amount of vitamin C shown in the table was derived, none had access to gardens or was able to obtain vegetables from the country or elsewhere. The general deficiency of calcium in all the diets was principally due to the complete lack of milk or cheese.

Factory Workers

Out of Vienna's population of 1,400,000 in Sept., 1945, about 250,000 ate a midday meal in a canteen for six days a week. In order to do this they sacrificed coupons representing 300 g. of bread. Most of the canteens were Werksküchen attached to factories or business houses. In addition there were a number of public canteens, where the sacrifice of 500 g. of bread weekly was demanded. The food supplies made available to canteens included not only the bread or flour obtainable from the coupons given up by diners but also an issue of 50 g. of pulses, 500 g. of potatoes, and an indeterminate supply of meat (usually horse) and other foods issued somewhat capriciously as stocks allowed on a special Bezugschein. Thus, people with access to Werksküchen got a better diet than that shown by their ration entitlement. Furthermore, although some of those who used canteens were doing heavy work, many were employed in banks or offices. It was therefore clearly of importance to investigate the nutritional value of the diet of this section of the population.

Surveys were carried out in two factories. The first was a marine engineering works and office in Bezirk III, and the second a big machine shop at Simmering, in Bezirk XI. In addition to a study of the diet of these two groups of works and an investigation of the canteen meals provided, the nutritional value of the meals issued from a large central kitchen in Bezirk V was also calculated. This kitchen was preparing about 50,000 meals daily, 27,000 of which were issued in insulated containers to 290 canteens in all parts of Vienna. The remaining meals were used to feed camps of refugees from Sudetenland. The nutritional value of the meals actually issued from the two factories and the central kitchen is shown in Table III. It can be seen from this table that the sacrifice of 300 g. of bread, providing 747 calories, represents a highly favourable exchange for six meals each of, say, 650 calories, or, in total, 3,900 calories.

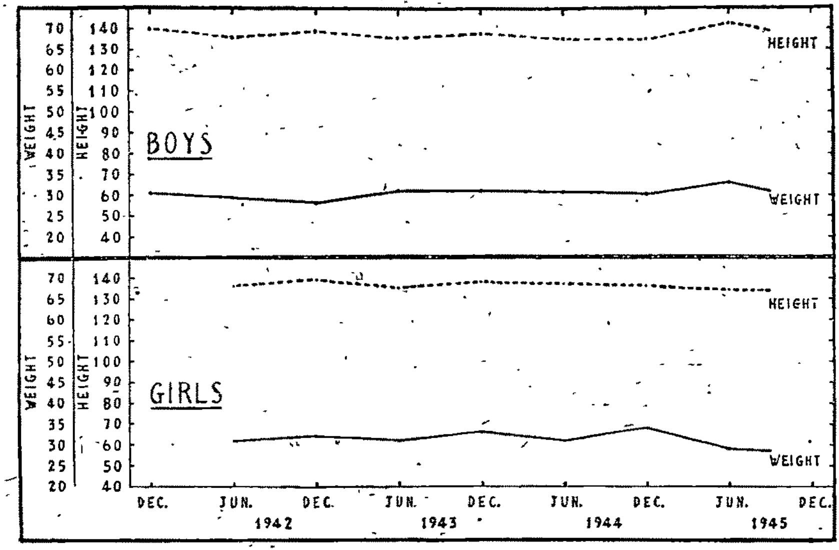

FIG. 2.—Average heights (cm.) and weights (kg.) of 10-year-old school-children in Vienna, Dec., 1941, to Sept., 1945.

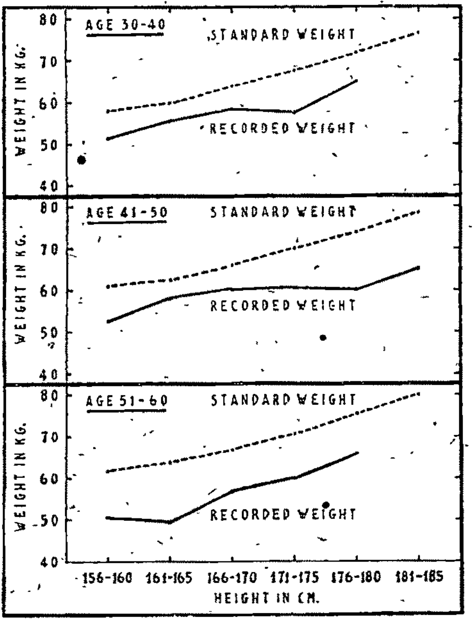

FIG. 3.—Heights and weights of male factory-workers in Vienna, Sept., 1945. (Based on the weights of 594 men.)

A group of employees at each of the two factories mentioned above was studied. Most of the individuals comprising these groups possessed workers' or heavy-workers' ration cards, entitling the holders to food providing 1,350 and 1,620 calories respectively. The right to hold such cards does not necessarily depend on the physical activity of the work done. Under the then current system, clergymen, municipal officials, senior police officers, people working in any capacity in hospitals, teachers, and many others are considered to be "heavy workers." In the two factories studied, although a certain amount of work, notably repairs to the factory buildings, was in progress, the general level of activity was not very high. The composition of the diets eaten is shown in Table IV.

In order to do a reasonable amount of physical work a man needs at least 3,000 calories. The figures above show, therefore, that the amount of food eaten in Sept., 1945, by workpeople in Vienna was not sufficient for active physical labour. The general character of the diet—its deficiencies in calcium and in Bezirk III in vitamin A—was, as would be expected, similar to that found in the case of normal consumers. The better distribution of vitamin C was largely due to the official issue of potatoes to canteens. Green vegetables and tomatoes—upon which, in the absence of dairy produce, the diet depends for vitamin A and to a lesser degree for riboflavin and other nutrients—were again available only from gardens, friends, or illegal sources, and were again more plentiful in Bezirk XI.

Children

The diets eaten by two groups of children 10 years old—20 boys and 20 girls—were investigated in two separate schools in Bezirk V. The results of this work are shown in Table V. The rations to which children of this age were entitled provided about 850 calories daily. Milk was available only for children up to 3, so that these 10-year-old boys and girls officially received none. Out of the 40 children examined, milk was reported in the diet of only 5, who had obtained what small amount they had consumed from brothers or sisters 3 years old or younger.

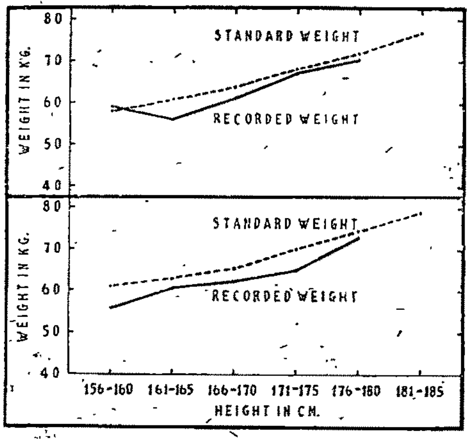

FIG. 4.—Heights and weights of coal-miners in Carinthia, Sept., 1945. (Average weight found from total of 282 men.)

From the figures given in Table V it can be seen that, although the give-and-take of family catering enabled them to get more to eat than their rations allowed, the children studied were receiving little more than half the 2,500 calories probably needed for proper growth, and that their diets were deficient in protein and riboflavin and seriously deficient in calcium.

The level of vitamin A and vitamin C was precariously maintained by off-the-ration vegetables and potatoes.

Body Weight

In an attempt to assess the effect of the food shortage in Vienna during the period from April to Sept., 1945, a series of body-weight records have been collected. Although the medical examination of school-children was reasonably well maintained during the course of the year, the collected records for the city for the period covered by the war appear to have been destroyed. It was found, however, that, at the two schools where the dietary studies were made, the children's biographical records, including their heights and weights, had been kept up to date. In Fig. 2 the average heights and weights of those children who were 10 years old at each of the dates shown have been plotted for the period from Dec., 1941, up to Sept., 1945. The general trend of these graphs suggests that, so far, no serious check in the growth of the children had occurred.

A second and more comprehensive record of body weights has been made of those employed in the large engineering works in Bezirk XI referred to in Table III. The heights and weights of the men, taken while they were wearing shirts and trousers and without shoes, are shown in Fig. 3, where they have been compared with standard British statistics for men of comparable age groups (Davidson and Anderson, 1940). From these observations it appears that, on the average, the men between 30 and 40 years of age were about 8 kg. under weight, and those between 40 and 50 and between 50 and 60 about 10 kg. under weight.

Fig. 4 has been included here as an interesting comparison and as a justification for using the British height–weight standards. It shows the body weights of a group of 282 miners at a brown-coal mine at St. Stefan, in Carinthia, one of the British-occupied provinces of Austria. When the weighings were made the men were receiving rations providing about 2,300 calories daily. The mine is situated in a rural district, and the quantity of unrationed food available at that time was estimated by supply officials to provide a supplement of about 800 to 1,000 calories daily. Thus the total food intake was greater than 3,000 calories. Since the men were weighed naked after having taken their baths, it appears that their weights closely approximated to the standard figures.

Discussion

The situation facing Vienna as winter draws nearer is a dangerous one. The sheer lack of calories shown by this September survey has been partially remedied by the provision of additional food, including meat, fats, and sugar. But the situation as shown by Fig. 1, although improved, is nevertheless precarious. The number of cases of hunger oedema for which extra rations were being provided by the Austrian authorities during the first weeks of October was from 200 to 300. This number from a city of 1,400,000 is not yet catastrophic, but shows that there is no margin to spare. The protein position has also been improved by the better rations; but supplies of milk for children, while increased, have not yet allowed any issue to be made to those over 6 years old, although it had been hoped to provide milk up to the age of 12. There is no issue of milk to adults, with the exception of a ration for pregnant women. To reduce the deficiency of calcium in the diet, which is primarily due to the lack of milk products, chalk is to be added to the flour.

For vitamin A and vitamin C, and to some extent for riboflavin, the Viennese diet depends entirely on potatoes and vegetables. Great efforts are being made to ensure that a ration of these items shall be distributed. Supplies of vitamin concentrates might serve as reinsurance.

Thus the position in Vienna this autumn has been assessed, and it is hoped that the action it has been possible to take can reasonably be expected at least to allow the population to subsist during the winter. The fact, however, must be faced that the level of nutrition upon which the Viennese must build their defences against cold and disease is dangerously low.

Summary

A dietary survey carried out in Vienna in Sept., 1945, at the beginning of British participation in the administration of the city showed that at that time the diet available to two random groups of normal consumers provided only about 1,000 calories; factory-workers were obtaining from 1,400 to about 1,800 calories; and children 10 years old about 1,300 calories. The adults' diets were deficient in calcium and often grossly lacking in vitamins A and C. The protein content of the children's diet was inadequate, owing in large measure to the fact that no milk was available for any over the age of 3 years. All the diets failed by a wide margin to provide the nutritional targets recommended by the U.S. National Research Council.

No pronounced drop was recorded in the heights and weights of the children studied. It appeared, however, that men working in a large factory in Vienna were on average from 8 to 10 kg. under weight.

This brief survey of the level of the diet in Vienna in Sept., 1945, underlines the difficulties and dangers likely to be encountered before winter is passed.

TOXIC EFFECTS OF 2,2-*bis* (*p*-CHLORPHENYL) 1,1,1-TRICHLORETHANE (D.D.T.) IN MAN

BY

R. A. M. CASE, Ph.D., M.B., Ch.B.

(*From the Royal Naval Physiological Laboratory*)

2,2-*bis* (p-chlorphenyl) 1,1,1-trichlorethane, more usually known as "D.D.T.," has now a wide application as an insecticide, and the general consensus of opinion is that, used with reasonable care, preparations containing D.D.T. do not present significant toxic hazards to human beings (Neal *et al.*, 1944; Cameron and Burgess, 1945). Nevertheless, Wigglesworth (1945) reports a case of presumed D.D.T. intoxication in a laboratory worker after deliberate exposure, and Cameron and Burgess emphasize the possible danger to operators using D.D.T. in an oily solvent. The danger of D.D.T.-poisoning following the application of this substance in acetone is stressed by Taylor (1945), who reported fatal effects in rabbits after dressing with a 5% solution and marked toxic effects after dressing with a 0.5% solution. The incorporation of D.D.T. in paints and distempers has now become an established procedure, and the practice seems likely to be extended in the future, for such paints appear to be efficient in the control of infestation by house-flies (Campbell and West, 1944).

D.D.T. has been shown to be toxic to a variety of mammals, including rabbits, guinea-pigs, rats (Draize, Nelson, and Calvery, 1944; Smith and Stohlman, 1944; Cameron and Burgess, 1945), cows, sheep, horses (Draize *et al.*, 1944), and cats (Lillie and Smith, 1944). The main pathological features seem to be liver damage of varying degree sometimes reaching the stage of necrosis, loss of weight, anorexia, mild anaemia with a reduction of the mean corpuscular haemoglobin, polymorphonuclear leucocytosis, and damage to the central nervous system, causing excitability, instability, tremors, and muscular weakness (Cameron and Burgess, 1945). No specific histological changes have been reported in the C.N.S., though various authors have noted some degeneration, vacuolation, pyknosis, and tigrolysis of a few anterior horn cells in the thoracic and lumbar regions (Cameron and Burgess, 1945; Lillie and Smith, 1944; Smith and Stohlman, 1944).

In the one case of human intoxication to be found in the literature Wigglesworth (1945) reports heaviness and aching of the limbs, sleeplessness, "spasms of extreme nervous tension," prostration of such a degree as to confine the sufferer to bed for a fortnight, and involuntary muscular twitchings over the whole body on at least three occasions. Full recovery had not taken place at the end of the year. The victim had been exposed to concentrations of D.D.T. in acetone and in powder form far in excess of levels that might reasonably be met with in the routine use of the insecticide. This report of Wigglesworth's is of great importance in that it removes the question of human D.D.T. intoxication from the sphere of theoretical speculation to the realms of industrial medicine; for it is likely that a substance known to be toxic to mammals, shown to be toxic to man under certain conditions, and in wide use may produce subclinical manifestations, not at present recognized, which will lower the health-level and efficiency of workers at risk, and that the rapidly growing use of D.D.T. will extend into circumstances where human intoxication is likely to occur.

In view of this increasing use of the substance, and the repeated warnings of the dangers of toxic effects, it is felt that it is desirable to publish the following work, undertaken for Service reasons during the early part of this year. If the design of the experiment seems somewhat narrow, it should be realized that this is because an answer to a specific problem was wanted and many aspects had to be ignored.

The problem under investigation was the possible toxic effect of the use of a distemper containing 2% by weight of the dry film of D.D.T. in circumstances where the paint would be inevitably covered with a thin film of oil, the ambient temperature would be such that personnel at risk would be largely unclothed, their skin would be oily and sweaty, because of cramped accommodation large areas of oily skin would come into contact with the paint, and efficient washing of the body surface could take place only at relatively infrequent intervals. Any toxic effect manifested would be a serious matter, for not even the slightest lowering of efficiency of the personnel could be tolerated, and even the least functional damage to the C.N.S. would assume a serious aspect.

Experimental

Two subjects were employed in this investigation: R.A.M.C., male, presumably healthy; and A.I., male, also presumably healthy. The desired environment was secured by using a steel chamber, octagonal in plan, six feet across and six feet high. A heater was installed, and a blower fan could be controlled from inside. A narrow steel seat ran round the inside of the chamber, and a small bench was installed upon which the necessary manipulations could be performed during the sojourns. The chamber walls were distempered at first with a normal distemper and later with a similar distemper with the addition of D.D.T. An analysis of this distemper (dried film) is given in Table I. The surfaces were then covered with a thin film of lubricating oil. Two sojourns, each of 48 hours' duration, were made, with an interval of 48 hours between. On the first occasion the chamber was painted with the distemper without D.D.T., and on the second with the distemper containing D.D.T. Both subjects wore short trunks only, and were forced to sit so that a large skin area, chiefly of the back, was always in contact with the oily walls. It was found possible to sleep on the narrow seat, alternate watches being taken.

TABLE I.—*Analysis of D.D.T. Distemper*

Water	39%
Oil-modified phenolic resin	10%
Siliceous matter (china clay), yellow ochre (Fe_2O_3), titanium dioxide	49%
D.D.T.	2%

In addition the film contained very small quantities of a chlorinated phenol and a compound or substituent of ammonia as preservative and dispersing agents.

Carbon dioxide was absorbed by means of a protosorb canister, and air analyses showed that during both experiments the carbon dioxide content of the air did not rise above 1% and the oxygen content did not fall below 19%. The heater and blower were manipulated so that the temperature ranged between 25 and 30° C. dry bulb, and 24 and 28° C. wet bulb (relative humidity 88–94%), thus providing a high air temperature and high humidity.

The following observations were made:

Clinical neurological examination before the control experiment, after the control experiment and before the D.D.T. experiment, immediately after the D.D.T. experiment, and again 5 days after the conclusion of the experiment.

Electro-encephalograms were made at the same times.

Haematological examinations were made every 24 hours during both experiments and for the succeeding 5 days, and weekly thereafter up to 47 days. The criteria employed were erythrocyte counts; haemoglobin estimations, performed by the alkaline haematin method of Clegg and King (1942), the solutions being evaluated on a "Spekker" photo-electric absorptiometer and an Ilford "604" "spectral green" filter; reticulocyte count; siderocyte count, using αα′ dipyridyl-thiocyanate staining technique (Case, 1944) and the inverse binomial sampling method (Haldane, 1945); leucocyte count and differential leucocyte count, using Leishman-stained preparations. From these data the mean corpuscular haemoglobin and the haemodynamic index (Case, 1945) were calculated.

Urine analyses were conducted before and after each experiment and at intervals during the succeeding days, and the blood pressure was recorded at similar times.

Careful notes were taken of any subjective phenomena observed. The results of these investigations are summarized in Tables II to VIII.

	3	Smarting of eyes. A further period of "yellow vision" lasting 30 minutes. Feeling of tiredness, touchiness, and mental incapacity	Smarting of eyes. "Touchiness"
	4	Tiredness. A feeling of muscular incoordination and lack of concentration. An "apprehensive" mental state. Some "heaviness of limbs"	Tiredness. Lethargy with "apprehensive" mental state and "touchiness"
	5	Pain in limb muscles, feeling of inability to walk properly. Pain in left wrist and feeling of loss of extensor power. Extremely irritable, with marked mental incapacity	Tiredness and pains in limbs. General feeling of "illness" so marked that subject felt compelled to remain in bed. No obvious clinical signs
	5–12	Pains in limbs and especially left wrist persisted. Radiograph of wrist on 12th day: N.A.D. Fibrillation of both triceps brachii observed on three occasions during this period. A curious feeling when walking, as if the knees were bending backward, which became known as "goat-leg." This was most marked when ascending steps	Pains in limbs and right shoulder-joint. A general ill-defined malaise, with mental irritability and some mental incapacity
	12–33	The above symptoms persisted, gradually becoming less marked, during this period	Gradual improvement during this period
	33–47	None	None

My colleague, Surg. Lieut. C. C. Evans, R.N.V.R., reports upon the electro-encephalograms as follows. "Electro-encephalograms were taken on both subjects at the following times: (1) 24/5/45—before starting experiment; (2) 28/4/45—after 48 hours in the chamber without D.D.T. paint; (3) 31/5/45—immediately after 48 hours' confinement with D.D.T. paint; (4) 5/6/45—5 days later. No alterations of any significance were observed between the successive records taken."

Neurological Examination

The following were investigated: Cranial nerves, reflexes (biceps, supinators, knee-jerks, ankle-jerks, abdominals, cremasters, and plantars), motor power of limbs, sensation (pinprick, cotton-wool, and vibration), joint position sense, dysdiadokokinesis, hand tremor, finger-nose test, and Rombergism. Tables VI and VII show only those tests where some abnormality was found in one or both subjects.

Discussion

The protocols show that during the control period no measurable changes took place apart from a fall in *p*H in the urine. After exposure to D.D.T. distemper, however, various changes did occur. The most dramatic of these, as might be expected, were found among the subjective phenomena noticed. The smarting of the eyes was due to some lacrimatory substance given off by the paint, although 48 hours had been allowed for drying, with the chamber doors open and the blower on. This substance was most noticeable near the roof. Air from this area was frequently bubbled through silver nitrate solution and acid potassium chlorate–soluble starch solution, but no free HCl or chlorine was detected by the procedure. The vapour was slightly acid to litmus paper, so it was unlikely to have been the ammonia. The smell was reminiscent of dettol. I am of the opinion that this lacrimatory substance was more likely to have been the trace of chlorinated phenol added as a preservative than a product of the D.D.T., but the experiment afforded no direct evidence upon this point. The tiredness, heaviness, and aching of the limbs were very real things, and the mental state also was most distressing. Not only was a state of extreme irritability present, but also both subjects had a great distaste for work of any sort and a feeling of mental incompetence in tackling the simplest mental task. This mental incompetence was more apparent than real, for one of the subjects (R.A.M.C.) forced himself to undertake some mathematical calculations, and was able to perform them with normal precision. The joint pains were quite violent at times, and subject R.A.M.C. went to the length of having his wrist radiographed, even though it was thought extremely unlikely that any abnormal findings would be reported. Subject A.I. was so prostrated that he had to take to his bed for a day. He is far from being a hypochondriacal type, and in fact prides himself upon his ability to endure hardship and discomfort. No explanation is offered for the transitory "yellow vision," but again it seemed a very real thing at the time. On the whole, these subjective findings tally well with the symptoms described by Wigglesworth (1945), and even in an attenuated form would be serious in Service personnel.

The neurological data are of interest in that they do show some slight evidence of measurable change—in the diminution of reflexes, the alteration in auditory acuity in both subjects, and in the patchy peripheral anaesthesia produced in one subject. The production of a fine tremor in one subject is also probably significant.

The urine analyses show a progressive fall of urinary *p*H, but this change also occurred to a smaller degree in the control experiment, and little diagnostic importance is attached to it. The appearance of a marked indicanuria is more likely to be significant, and it is of interest to notice that Stewart *et al.* (1945) consider this test to be of value in early T.N.T. poisoning.

The blood-pressure records are of considerable interest, since a marked transitory fall of systolic pressure was observed in both subjects, one of whom (A.I.) normally has a low diastolic pressure. No explanation is offered for this finding.

In the haematological investigations lay our main hope of finding useful criteria for following toxic change if it should occur, since haematological changes had been reported in mammals. Furthermore, haematological examinations are a practical means of assessing toxic damage of small degree in large groups of people, and if toxic effects were to be discovered it would become important to find a practicable diagnostic and prognostic index applicable to a population at risk.

The data show that shortly after exposure to D.D.T. there is a diminution of the mean corpuscular haemoglobin. This is a more accurate index than erythrocyte counts or haemoglobin estimations alone, since the figures are unaffected by changes of blood volume. A fall in M.C.H. was found in mammals by Cameron and Burgess (1945) and also in early T.N.T. poisoning by Stewart *et al.* (1945). The change occurs so rapidly that it cannot be due to a formation of hypochromic cells in the bone-marrow, so that the red cells must lose haemoglobin. The mechanism by which this occurs is almost certainly an intracorpuscular degradation, the later stages of which are shown by the appearance of stainable non-haematin iron within the cell (Case, 1943, 1945a). If this is so, then some of these cells (siderocytes) should be found in the circulation in excess of normal levels (0.5% ± 0.25%: Case, Ladan, and Nutt, 1945). The siderocyte figures show that this is indeed the case, and suggest that the siderocyte level might be an extremely useful index. This index is already employed in the control of lead-poisoning (Case, 1945; Case, Scott, Scott, and Woolf, unpublished work). The reticulocytes also show a rise, and although the haemodynamic index (Case, 1945) shows a depression followed by a return to normality, it still lies between its normal values of 1-5. This index is an expression of the dynamic activity of the erythron, and while the index is in the range of normality a progressive haemolytic condition need not be feared.

The changes in the white cell counts are at variance with the findings of Cameron and Burgess (1945), who considered that a rise in white cell count with an absolute polymorphonuclear leucocytosis might be a sign of diagnostic importance. In our two cases there was no significant change in the leucocyte count, but after exposure to D.D.T. there was a transitory polymorphonuclear leucopenia and an increase of lymphocytes. In one subject (A. I.) this was followed by a leucocytosis and polymorphonuclear leucocytosis. In the other subject a lymphocytosis persisted throughout the period of observation. This may be due to the fact that this man had suffered from infective mononucleosis three years ago, and since then has had a tendency to time-lag in recovery from induced polymorphonuclear leucopenia.

On the third day after exposure, at a time corresponding to the polymorphonuclear leucopenia, small numbers of immature granulocytes (myelocytes in the Schilling haemogram classification) appeared, but their incidence lasted for three days only. At about the same time occasional nucleated red cells could be found in the blood films.

With the exception of the leucocyte curves, the response of both subjects was of an essentially similar nature, and by the 26th day a return to the original limits was reached for most of the haematological criteria employed.

Conclusions

This work shows that under certain conditions a preparation containing 2% of D.D.T. may, in the presence of oil, constitute a serious hazard to men at risk. The work also suggests that haematological examinations, employing siderocyte levels; haemoglobin and red cell estimations; reticulocyte counts and leucocyte counts, and also urinary indoxyl sulphate estimations might all be useful tests in the prevention or early diagnosis of D.D.T. intoxication.

It should be stressed that these experiments only show D.D.T. distemper to be toxic under special conditions, possibly rather more severe than would obtain in practice, and do not form the basis for any condemnation of the widespread use of D.D.T. if proper precautions are taken, particularly in the avoidance of oil contamination. They do, however, emphasize that D.D.T. intoxication in human beings is a hazard to be considered and guarded against.

Summary

Exposure of two subjects for 48 hours under special conditions (oily surface, large skin areas exposed, high ambient temperature, and relative humidity) produced definite toxic effects, including an increase of erythrocyte destruction (siderocytosis), a decrease in the mean corpuscular haemoglobin, an increase in reticulocytes, a slight fall in haemodynamic index, a diminution of polymorphonuclear neutrophil leucocytes accompanied by the appearance of immature white cells, the appearance of indoxyl sulphate in the urine, tiredness, heaviness, and aching of the limbs, diminution of some reflexes, unilateral slight impairment of hearing, transient "yellow vision" (one subject), muscular fibrillation (one subject), peripheral patchy anaesthesia (one subject), weakness of the legs, and a curious apprehensive mental state. A return to normality took between 26 and 33 days.

The significance of these findings is discussed, the relative merits of the examinations used are considered in relation to the control of D.D.T. intoxication, and the danger of D.D.T. in the presence of oil is emphasized.

I should like to take this opportunity of expressing my appreciation of the co-operation received from my colleagues, and wish to thank Mr. H. V. Hempleman, B.A., for the gas and urine analyses; Surg. Lieut. C. C. Evans, R.N.V.R., for the neurological examinations and electro-encephalograms; the radiologist, Surg. Cmdr. D. A. Inire, R.N.V.R., R.N. Hospital, Haslar, for the *x*-ray examination; and most particularly my technician L.S.B.A. A. Ireland, for his cheerful collaboration as an experimental animal and his careful and conscientious examination of material.

A FATAL CASE OF D.D.T. POISONING IN A CHILD

WITH AN ACCOUNT OF TWO ACCIDENTAL DEATHS IN DOGS

BY

K. R. HILL, M.B., B.S.
Major, R.A.M.C.

AND

G. ROBINSON, M.B., B.Ch.
Colonial Medical Service

We record what is probably the first fatal case of D.D.T. poisoning in man. In addition we describe the death of two dogs following skin-absorption of that substance. The toxicity of D.D.T. has been studied in human beings by Cameron and Burgess (1945) and Draize *et al.* (1944) by means of skin-application tests, and Neal *et al.* (1944) by means of mists and aerosols. Wigglesworth (1945) has described the toxic reactions to absorption through the skin in one human case.

D.D.T. Poisoning in a Child

History.—On Aug. 22, 1945, at 11 a.m., a child aged 1 year 7 months, the son of a West African soldier, found a bottle of 5% D.D.T. in kerosene and drank about 1 oz. Within 10 minutes he began to cough and vomit violently, whereupon he was given palm-oil by the neighbours. In a short while coughing and vomiting ceased, but his general condition worsened, and at about 12.30 p.m. he became comatose and had convulsions, which, so far as can be ascertained, consisted of generalized fine tremors. At about 1.30 p.m. he was taken to a near-by M.I. room, where he was seen by Capt. R. N. Johnston, R.A.M.C., who gives the following account: "The child was comatose and collapsed, with no perceptible pulse, and had froth at the mouth. Atropine 1/400 gr. was given and the stomach washed out, the stomach washing proving to be a yellow pultaceous mass of pawpaw (native fruit). No smell of kerosene was detected. Artificial respiration was given, but the child died at 3 p.m. (4 hours after drinking the D.D.T.)." Luckily, the bottle of D.D.T. was found shortly after the mishap, and the amount of D.D.T. ingested was fairly accurately deduced. It proved to be about 1 fl. oz. The 5% D.D.T. was made up of crude D.D.T. (100% commercially pure, setting point 100°) and crude kerosene.

Post-mortem Examination.—(Aug. 22, two hours after death.) The body of a well-nourished African child weighing 10 kg.; rigor mortis in lower jaw; froth at nostrils and mouth. Meninges: Excessive fluid in subarachnoid space. Brain: Congested, soft, and oedematous. Spinal cord: Normal. Thyroid and thymus: Normal. Trachea: Slight amount of froth and yellow vomit (pawpaw). Lungs: Pale, firm, oedematous, with one or two haemorrhagic areas. Heart: Slight excess of fluid in pericardial sac; otherwise normal. Stomach: Wall normal; contained pawpaw smelling faintly of kerosene. Small and large intestines: Normal. Pancreas: Normal. Liver: Congested, otherwise normal. Spleen: Twice normal size; on sectioning, cut surface was chocolate in colour, with well-marked raised grey Malpighian bodies. Kidneys and suprarenals: Normal. Sternal bone marrow: Normal. Cause of death: Pulmonary oedema.

Histology.—Frozen sections were stained with Fett-Ponceau Sudan IV, and paraffin sections with haematoxylin and eosin. Liver: Congested; cloudy swelling of hepatic cells; sinusoids dilated, contained fibrin, R.B.C.s, and a moderate number of leucocytes; some periportal leucocytic infiltration. Kidneys: Patchy congestion, glomeruli and tubules normal. Lungs: Alveolar oedema, with a few areas of alveolar haemorrhage and infiltration with polymorphs. Heart muscle: Interstitial oedema, with a mild interstitial inflammatory reaction. Spleen: Congested; Malpighian bodies large and showing many endothelial cells. Suprarenals: Normal. Stomach, caecum and ileum, thyroid and parathyroid: Normal. Pancreas: Cloudy swelling. Cerebrum, cerebellum, pons, and spinal cord: Normal. (No special staining for nervous tissue other than H. & E. and Sudan IV.)

At first there was some doubt as to whether death was due to D.D.T. or to the kerosene. To decide this the following experiments were carried out.

Experiment I

Two baboons, weighing 7 lb. (3.2 kg.) each, were selected, and the first was given 15 c.cm. of 5% D.D.T. in kerosene and the second 15 c.cm. of kerosene alone, by stomach tube. Within half an hour the first monkey became quiet, had ruffled hair, and was obviously ill. At two hours he had recovered, and appeared well 28 days later. The second monkey was unaffected.

Experiment II

To a baboon weighing 7 lb. (3.2 kg.) 30 c.cm. of 5% D.D.T. in kerosene, and to another weighing 6 lb. (2.7 kg.) 25 c.cm. of kerosene, were given by stomach tube. Within a quarter of an hour the former monkey had lost the use of his hind legs and was seen dragging himself with his fore-limbs. Convulsions developed, and there were fine tremors of the muscles of the legs, tail, and back. After one hour he died, with bloody, frothy fluid at the mouth and nares, cessation of respiration occurring while the heart was still beating. The second monkey was unaffected, and was alive and well 20 days afterwards.

Necropsy.—(Immediately after death.) Trachea: Contained small amount of frothy haemorrhagic fluid. Lungs: Showed massive haemorrhages with a small amount of oedema. Stomach: Distended with a pultaceous mass of half-digested peanuts smelling of kerosene; mucosa normal. Large and small intestines, liver, spleen, kidneys, suprarenals, pancreas, heart, and brain presented no abnormality.

Histology.—Liver: Hepatic cells showed cloudy swelling; dilated sinusoids containing fibrin; no leucocytic reaction other than a small amount of periportal small round-cell infiltration. Kidneys: Glomeruli congested; blood in capsular space; tubules showed cloudy swelling and granular degeneration with commencing disintegration of epithelium into lumen; many tubules contained blood casts. Lungs: Alveolar haemorrhage and oedema. Heart muscle: Normal. Spleen: Well-marked Malpighian bodies; normal. Stomach, caecum and ileum, pancreas, suprarenals, cerebrum, cerebellum, pons, and spinal cord: Normal. (No special nervous tissue stain used other than H. & E. and Sudan IV.) Cause of death: Pulmonary oedema and haemorrhage, following gastric administration of D.D.T. in kerosene.

D.D.T. Poisoning in Two Dogs

Two bull-terriers suffering from demodex eczema, with skins denuded of hair and ulcerated, were sprayed once with 5% D.D.T. in kerosene. Both dogs subsequently became very ill and lost appetite and weight, dying from exhaustion about two months later. Trypanosomes (*congolense*) were found in the blood of one dog immediately before death. No necropsy was performed on this animal.

Histology.—Liver: Widespread focal and centrolobular necrosis; the necrotic zones had many areas of calcification. Liver cells outside the necrotic zones showed cloudy swelling and fatty degeneration. No obvious leucocytic infiltration periportall or in the necrotic areas Some liver-cell regeneration, but no fibrosis around the damaged areas. Kidneys: Congested; glomeruli engorged and in some cases showing early hyalinization; marked tubular degeneration; all elements of the tubules were affected with cloudy swelling, fatty degeneration, colloid droplet formation with disintegration of the epithelium into the lumen; some tubules showed calcification; many casts. (Some of the R.B.C.s looked sickled.) Lungs: Oedematous, with areas of alveolar haemorrhage and leucocytic (mononuclear) infiltration. Spleen: Congested and presenting areas of haemorrhage; the Malpighian bodies showed proliferation of the endothelial cells, which contained pigment. Brain: (hippocampus) vessels engorged; no cuffing; no Negri bodies.

Discussion

The experiments on monkeys show that the cause of death in the child was due to D.D.T. rather than to the kerosene. A fairly accurate estimate of the toxic dose for a child can be arrived at. About 30 c.cm. of 5% D.D.T. solution was ingested by a child weighing 10 kg., which suggests a *lethal dose of about 150 mg./kg.* body-weight.

Smith and Stohlman (1944) gave a 1 to 5% solution of D.D.T. in olive oil by stomach tube to rats and rabbits, and assessed the L.D. 50's as 150 and 300 mg./kg. respectively. Woodard *et al.* (1944), using D.D.T. dissolved in corn-oil administered by mouth in one single dose, found that the approximate M.L.D. was: rats, 200; mice, 400–500; rabbits, 400 or over; and guinea-pigs, 250–600 mg. per kg. The lethal dose in our experimental monkeys proved to be more than 236 mg./kg. and less than 472 mg./kg. From this and the other experiments quoted above it would seem that the human subject is more sensitive to D.D.T. than the animal when the insecticide is dissolved in an organic solvent and ingested by mouth. In the case of the two dogs the toxic dose was not ascertained, but the cases are a reminder that D.D.T. dissolved in organic solvents appears to be easily absorbed through the skin and may prove dangerous (Draize *et al.*, 1944; Cameron and Burgess, 1945), though there seems little danger from the use of the powdered form or watery suspension. It is, moreover, noted that the two dogs had only one application of D.D.T. in kerosene, producing a similar finding to that of Taylor (1945), who reports the toxic effects of D.D.T. in acetone after one application to the skin of rabbits.

The symptomatology agrees with that described by various workers with a variety of animals. The child became comatose after a short lapse of time, but hearsay evidence suggests that at one period he had developed fine tremors. Fine tremors were also seen in the monkey, associated with loss of power of the hind limbs—a sign which has been observed by almost all authors in their animal experiments. The dogs showed the signs of chronic poisoning, consisting of loss of appetite and weight and poor health. Death in both the child and the monkey was due to respiratory failure, but in the case of the two dogs it was the result of chronic toxaemia leading to liver and kidney damage. Both the child and the monkey died rapidly, and therefore one would expect little damage to be apparent histologically. The dogs showed marked centrolobular necrosis of the liver and tubular degeneration of the kidneys, both with calcification, which is in accordance with the findings of Cameron and Burgess (1945) in their animal experiments. It should be noted, however, that the animals died two months after one application of D.D.T. in kerosene, whereas in other animal experiments chronic poisoning was induced by repeated daily skin applications. This therefore suggests that the dogs received a very severe initial injury to liver and kidneys, which subsequently progressed to a fatal termination. That this is not always the case is perhaps shown in Wigglesworth's (1945) human case of chronic poisoning from skin absorption of D.D.T. in acetone, in which the patient ultimately recovered. It has also been shown in animal experiments by Cameron and Burgess (1945) that when recovery takes place it does so without any subsequent demonstrable liver lesion.

Summary

The clinical and pathological aspects of a fatal case of poisoning in a child after ingestion of D.D.T. are described.

Death was due to pulmonary oedema, probably from paralysis of the respiratory centre.

The lethal dose was approximately 150 mg./kg. body-weight of commercially pure D.D.T.—an amount somewhat less than that found for experimental animals.

Two fatal cases of chronic D.D.T. poisoning in dogs are described, with a histological picture of centrolobular necrosis of liver and tubular degeneration of kidney with marked calcification.

We wish to express our thanks to Prof. G. R. Cameron, University College Hospital, for his advice on writing this paper and for assistance with the histology of our material.

OBSERVATIONS ON KERATOCONJUNCTIVITIS

(CASES SEEN IN MILITARY HOSPITALS)

BY

R. J. BUXTON, M.B., B.Ch., D.O.M.S.

Major, R.A.M.C.; Ophthalmic Specialist, 95 British General Hospital

This paper concerns 42 cases of keratoconjunctivitis seen in various military hospitals between Oct., 1943, and Feb., 1945. Details of the clinical features, investigations, course, and treatment are recorded; an endeavour has been made to demonstrate a dental or an ear, nose, or throat toxic focus as a causal factor in a portion of the cases.

Clinical Features

Previous Attacks.—Four patients reported earlier attacks in one or both eyes; the number would probably have been higher with further questioning, but care was taken to exclude previous attacks of other external ocular diseases with similar symptoms.

Onset.—The onset was usually acute, with lacrimation, photophobia, blepharospasm, and conjunctival discharge. Sometimes it coincided with another disease—e.g., malaria, tonsillitis, antritis. Disturbance of vision was unusual.

Lesion.—A varying degree of involvement of the cornea occurred in every case. With simple conjunctivitis there may be oedema of the epithelium and Bowman's membrane. Although such oedema sometimes occurred, it was typical of the cases under review to find punctate marginal corneal lesions. These varied from a spot just visible to the naked eye to one which was 1 mm. in diameter. They were commonly 1 to 2 mm. from the limbus, but could be up to 3 mm. away. They involved the epithelium, Bowman's membrane, and the superficial layers of the substantia propria. Loss of epithelium with the formation of shallow ulcers did occur, but this was unusual. Phlyctenular keratoconjunctivitis, superficial punctate keratitis, and conjunctivitis with marginal corneal ulcers should not be confused with this condition. Cases of keratitis with lesions scattered over the cornea were similar, and the dividing lines between such a keratitis, conjunctivitis with marginal ulcers, and cases of keratoconjunctivitis were difficult, if not impossible, to draw; the conjunctival discharge in the early stages and the lack of visual disturbances were distinguishing features. Both eyes were affected in four cases.

Associated Lesions.—Six cases had associated blepharitis, and skin conditions such as impetigo, external otitis, and dermatitis of face also occurred.

Investigations

Pathological Tests.—The white blood count varied between 9,850 and 13,000 per c.mm., with some increase in the polymorphs. The blood sedimentation rate was usually normal, and rarely rose above 4. Cultures from the conjunctival sac were sterile as a rule, but streptococci and staphylococci have occasionally been grown. It was noticeable what different results were obtained from different laboratories. I have discussed this with several pathologists, and it seems that certain points in connexion with conjunctival swabs should be emphasized. The swab may contain few organisms; it soon becomes dry and the organisms may get chilled and die. In taking the swab excess of tears should be removed, and the stick should be given a twist as the swab passes along the lower fornix. A culture plate should be inoculated and placed in the incubator at the earliest possible moment. Attention to these points should give the organisms the best opportunity to survive and grow.

E.N.T. Examination.—All cases were examined to exclude any ear, nose, or throat focus or sepsis. If such was discovered the next step was to decide what, if any, relation it had to the eye condition. In 17 cases some kind of toxic focus was found. These consisted of tonsillar infection (12 cases), antral infection (1 case), laryngitis (1 case), myringitis (1 case), and rhinitis (2 cases. In some of these, other parts were simultaneously inflamed to a mild degree—e.g., a subacute rhinitis with a septic tonsil. Tonsillar infection was not only present with obviously septic tonsils but, to an equal degree of importance, with small flat tonsils, tonsils which looked normal but from which pus could be expressed, and tonsillar remnants after a previous tonsillectomy; but if the patient had had recurrent attacks of keratoconjunctivitis, or attacks following tonsillitis, then, in the absence of another toxic focus, tonsillectomy was seriously considered. A controversial point should be mentioned here—the existence or otherwise of a quiet sinusitis, with neither symptoms nor positive findings, and a normal *x*-ray appearance. It is possible that such does occur, and, if so, it is relevant to this discussion as a possible toxic focus. Also, at times when *x*-ray facilities were limited, an ethmoidal or sphenoidal infection could not be definitely excluded.

Dental Examination.—All cases were examined to exclude a possible dental focus of sepsis. The following conditions were suspicious on clinical examination and confirmed by radiographs: (1) chronic pyorrhoea, with associated pus formation around tooth roots; (2) chronic granuloma, with or without a discharging sinus; (3) chronic sclerosis of tooth roots and surrounding bone, found in association with root fillings and heavily filled teeth. A mouth was often apparently healthy but on radiographic examination revealed hidden sepsis—e.g.: (1) a tooth root remaining after extractions—these often had apices projecting into the antrum; (2) granuloma of tooth root; (3) common dental cyst. The upper premolar and first molar teeth probably caused most of the trouble, their slender roots often extending to the antral floor. Eleven cases had dental lesions severe enough to be, in each case, a likely focus; 2 other cases needed dental treatment other than fillings of cavities, but simultaneously each had an E.N.T. focus which was considered a more probable cause. No cases of severe dental caries were seen, and mouths only needing odd fillings were not suspected; similarly, a limited degree of pyorrhoea did not cause trouble.

Treatment

Proflavine lotion 1/2000, penicillin drops (1000 units to 1 c.cm.), penicillin cream (500 units to 1 g.), pencillin powder, 10% protargol, 20% argyrol, 1/2000 and 1/1000 proflavine, 1/8% zinc sulphate, 1/2% atropine drops (in severe cases), painting the lids with 1% silver nitrate, hot bathings, have all been used. Although it seemed that the conjunctival discharge subsided more quickly with treatment, none of these drugs appeared to have any noticeable effect in shortening the course of the malady. When the cornea is much involved atropine helps to relieve pain and hasten resolution.

Course of the Disease

The duration varied between 3 and 64 days, with a mean of 16.8 days. Conjunctival discharge was usually present for 2 to 8 days, leaving hyperaemia only. This hyperaemia remained while the cornea continued to be inflamed, and traces could be seen for some time after. The corneal lesions were replaced by minute nebulae or disappeared altogether.

Several patients underwent tonsillectomy, and in some cases the eye condition showed an immediate improvement, and subsided more quickly than in the ordinary course of the disease. Occasionally there was an exacerbation of the ocular inflammation—possibly an allergic manifestation from a bacteriaemia; blepharitis also occurred after tonsillectomy. Similar improvement and occasional exacerbations were noticed after dental treatment—e.g., extraction of tooth root, dental extractions for apical abscess or pyorrhoea.

Conclusions

A scientific paper written under active service conditions must often be incomplete. The lack of a slit-lamp for corneal examination was keenly felt, colleagues for special examinations and laboratory facilities were not always available, cases could not be followed up for more than a brief period, the clinical entity of the disease is not always easy to recognize, and a reference library is not available. A noticeable proportion of the patients had an ear, nose, or throat toxic focus, 40% of sufficient severity to be suspected as the cause, and a similar proportion (26%) had a dental focus.

Final proof as to the cause could not be obtained, but the results were striking enough to justify investigation and treatment of toxic foci in all cases of the disease. If such is not done, it is probable that many cases will be insufficiently treated and may relapse, causing an unnecessary wastage of man-power from the need for further in-patient treatment. A possible cause having been found, it is not always a simple matter to decide how much mischief it is causing, and whether it needs drastic treatment, or any treatment at all.

My thanks are due to Capt. A. Smith, A.D. Corps, for his valuable co-operation on the dental aspect of the subject.

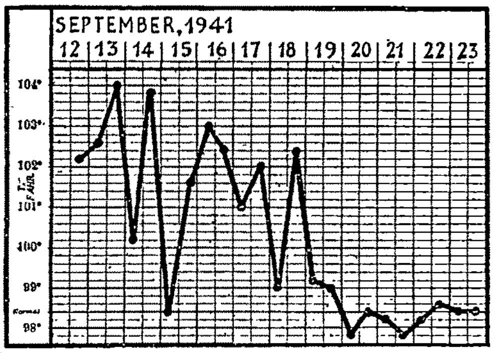
Medical Memoranda

A Case of Tick Typhus in the Sudan

Below is the history of the first case of tick typhus to be reported in the Sudan.

CASE REPORT

The patient, an English school-teacher aged 32, was admitted to Juba Civil Hospital on Sept. 16, 1941, complaining of fever and frontal headache of 7 days' duration. He was in good health until the evening of Sept. 9, when after a somewhat busy day he felt "rather weary and a trifle under the weather." On Sept. 10 he motored 100 miles over a bad road, and that night slept badly, awakening next day with a slight headache, but was still able to carry on with his work of inspecting bush schools. That evening he had abdominal pain and slight diarrhoea, and spent another restless and disturbed night. On the 12th he still felt ill, but was able to do his work. At the end of the day he felt "dead beat and really rotten." He took his own temperature at 8 a.m., and found it to be just over 102° F. On Sept. 13 the morning temperature was 103.6° F., and he felt too ill to leave his bed. He was seen by a doctor, who diagnosed malaria and treated him with mepacrine; the blood film was, however, negative. On the 14th and 15th he felt much the same, and on the 16th was transferred to Juba Civil Hospital. On arrival (11 a.m.) his temperature was 103° F., pulse rate 64, and respiration rate 21. He looked well nourished and had a sallow complexion (normal for the patient), but was obviously ill. The skin of both forearms, anteriorly and posteriorly, was covered with a dull pink maculo-papular rash, some of the papules showing vesication. The rash was also present on the trunk and abdomen, but was much more scanty; it was not present on the face. The macules faded on pressure. The rash was first noticed by the patient that day. Below the right internal malleolus was a small sore (tache noire) about 2 cm. in diameter, covered with a thin scale; this was first noticed about the end of August, and had been dressed by the patient himself, who thought it was probably a mosquito bite. Both tonsils were slightly injected, there was conjunctivits, and the patient seemed to be a little deaf. He had been constipated for two days.



• A clinical diagnosis of typhus fever was made and mepacrine treatment was stopped. This diagnosis was confirmed by the pathological report received on Sept. 24. The blood culture was negative, but the Weil-Felix reaction was positive OX2 1 in 500, OX19 negative—a report diagnostic of African tick typhus. On the 17th and 18th his condition showed slight improvement, but he felt very tired and worn out. The rash now began to fade. On the evening of the 19th his temperature fell to 99° F. and was normal next morning. The pulse rate was never above 76, and was relatively slow for the degree of pyrexia—e.g., when the temperature was 103° F. the pulse rate was only 64. During the next fortnight he felt very weak and tired, but subsequent to returning to his home in Yei, on Oct. 3, he made a rapid and complete recovery.

The diagnosis was suggested to me by the typical appearance of the rash and the sore on the ankle, and was confirmed by the Weil-Felix reaction.

COMMENT

It is impossible to say where the patient acquired the disease, as he was on tour when he fell ill. He remembers being bitten on the ankle by an insect in Yei about the end of August; he also thinks he may have been bitten while staying in Juba on Sept. 4 and 5; after that time until his illness he was on tour on the east bank of the Nile, and sometimes had to walk through long grass, in which he might have collected a tick.

The main interest in the case is that it suggests tick typhus as a possible cause of some of the cases of undiagnosed pyrexia which are admitted to hospitals in this province, and emphasizes the importance of carrying out the Weil-Felix test in cases of pyrexia in which the diagnosis is in doubt. The diagnosis would probably not have been made had the disease occurred in a native of the Sudan; the rash would have been missed, and the case would have been called "clinical malaria" or "P.U.O."

My thanks are due to the Director, S.M.S., for permission to publish this case, and to Drs. Horgan and Kirk for the pathological findings and interpretation.

Juba. Senior Medical Inspector, Sudan Medical Service.

Ligature of Anterior Ethmoidal Artery for Arrest of Profuse Epistaxis

The case recorded below may be of interest as an unusual exercise in applied anatomy. For the arrest of profuse and intractable epistaxis, arterial ligature is occasionally indicated, and the great importance of the branches of the external carotid artery in the supply of the nasal cavity should not blind one to the fact that the upper and more inaccessible part of the cavity draws its arterial blood from the internal carotid by way of the anterior ethmoidal and its smaller companion, the posterior ethmoidal artery. For further amplification of these and other anatomical points I would refer to the instructive article by E. D. D. Davis (1939), which gave me the necessary inspiration to cope with this difficult case.

CASE HISTORY

On April 9, 1945, a man aged 44 was admitted for epistaxis. The bleeding had been severe and had lasted for five days. He had been admitted to another hospital, where the nose had been repeatedly packed and various styptics applied. A transfusion of two pints of blood had also been given. As the bleeding was not arrested he was transferred to this hospital.

On admission, though the patient looked pale and distressed, the bleeding had stopped. His haemoglobin was found to be 38%. The stale and offensive packing was removed from the right nostril. The nose was cocainized, and anterior rhinoscopy revealed a granular and inflamed mucous membrane, with many small abrasions, presumably the result of previous attempts at haemostasis. One small bleeding spot in the floor of the nose was touched with the cautery, though subsequent events showed that this was not the real source of the trouble. The nose was left unpacked, and two pints of blood were transfused.

No further bleeding was seen till four days later, when a copious flow occurred from the right nostril. This was controlled temporarily by firm packing with ribbon gauze soaked in liquid paraffin. Further severe bleeding followed an attempt, a few hours later, to remove the pack and deal locally with the source. The patient now showed all the signs of a severe loss of blood, and a fatal termination appeared imminent. A transfusion was begun and was maintained for 18 hours, five pints of blood being given. Under local analgesia, the bifurcation of the right common carotid was exposed, and the external carotid artery was doubly ligatured close above the origin of the superior thyroid artery. At the same time a loop of catgut was placed loosely round the internal carotid artery and the ends were brought out through the lips of the cervical skin incision, which was sutured. This catgut loop was not tied, and in no way obstructed the flow of blood through the internal carotid, but traction on the loop would act as a temporary ligature if the need should arise.

For two days the patient made good progress, but on the morning of the third day further severe epistaxis occurred from the right nostril. Gentle traction on the catgut loop stopped the bleeding at once. On releasing the tension on the loop, blood could be seen to well from the upper recesses of the right nasal cavity. With sufficient gentle traction maintained to stop the bleeding temporarily, the anterior ethmoidal artery was tied through an incision on the inner side of the orbit. This procedure, carried out under local analgesia, presented no difficulty, as it is a regular part of the commonly practised Ferris-Smith ethmoidal exenteration. Transfusion of another two pints was given.

No further epistaxis occurred. Four days after this second operation his haemoglobin had risen to 40%, and on his discharge from hospital on May 14 it had reached 70%. He has since remained free from nose-bleeding.

No cause could be found for the bleeding. There was no history of injury, and no local lesion or growth in the nasal cavity or in the nasal sinuses could be found. His blood pressure had never risen above 130/80, and an exhaustive examination of the blood showed no abnormality beyond anaemia and a slight polymorphonuclear leucocytosis, occasioned by the loss of blood: both have now returned to normal.

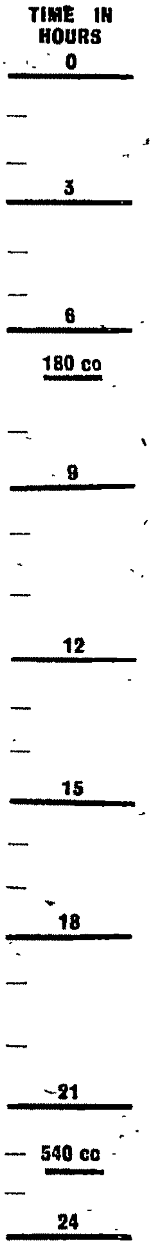
Administration of Penicillin by Intramuscular Drip



The use of the intramuscular route for the continuous infusion of penicillin (Morgan, Christie, and Roxburgh, 1944) has proved to be of value as an alternative method of administration in patients who cannot tolerate intermittent intramuscular injection. The amount of fluid that can be absorbed readily by a muscle in 24 hours is one pint or less, and in June of last year the need arose for a simple method of administration which did not require special equipment or experience. A description of the technique outlined below was therefore circulated by the Penicillin Clinical Trials Committee of the Medical Research Council to all hospitals likely to receive battle casualties. Many thousands of the graduated labels have been issued, and we understand that their use is still recommended in the Army. The method has several advantages over those which require special equipment (McAdam, Duguid, and Challinor, 1944; and Hill, 1944). Its simplicity is its main asset.

The graduated scale (as shown in the illustration), which is printed on gummed paper or copied on sticking-plaster, is attached to the standard E.M.S. transfusion bottle so that the 180 c.cm. and 540 c.cm. marks correspond with those on the bottle. A 24-hours supply of penicillin is dissolved in 540 c.cm. of sterile normal saline, and the drip set up in the usual way at 8 to 12 drops a minute. The needle is inserted diagonally into the lateral aspect of the thigh, secured with sticking-plaster and covered with a sterile dressing. The fluid level should be inspected every hour or so, and should correspond with the appropriate mark on the scale; if it does not, the drip should be adjusted.

No special claims are put forward for this method of administration. Its merits lie in simplicity and cheapness. The disadvantage of the method is that 540 c.cm. of fluid are given as an infusion every 24 hours. This can be reduced by putting two days' supply of penicillin into the bottle and doubling the time scale, thus making a pint last 48 hours. Using this method we have not failed to obtain an adequate blood concentration of penicillin.

These labels may be obtained from Messrs. A. Richardson, Ltd., 5, High Street, St. Albans. Alternatively the figure, which is reproduced full size, may be copied on sticking-plaster.

Reviews

TECHNIQUE IN TRAUMA

Technique in Trauma. Planned Timing in the Treatment of Wounds, including Burns. By Fraser B. Gurd, M.D., C.M., and F. Douglas Ackman, M.D., C.M. (Pp. 68; illustrated. 15s.) London: William Heinemann Medical Books. 1945.

This monograph from the Montreal General Hospital is made up of three articles and a summary. The first two deal with burns, and the third with wounds in general. This last section is in accordance with principles generally accepted in this country but, being written before penicillin was generally available, it is now in need of elaboration.

The sections on burns are well documented, and the modesty of the writing is particularly attractive after the rather polemical views put forward by advocates of different methods of treatment in the past. The authors advocate a special organization for treatment of burns which would have the support of anyone who has had to take charge of these cases. It need be neither large nor elaborate. Infrequent dressing, after cleansing, with sulphathiazole emulsion, followed by early grafting, is the keynote of their local treatment. The full case records are of special interest in so far as the patients were civilians, and most of them came for treatment early without the long gap imposed by wartime transfers of casualties. It is encouraging to read of the high degree of success achieved.

This monograph is well worth reading because of its detail, its honesty, and the self-criticism which the authors have included. It is strictly practical, and the experienced can appreciate difficulties described and overcome and learn something new, while any who have only a limited experience in the treatment of burns can use the details as a safe guide.

DISEASES IN THE TROPICS

Diagnosis and Treatment of Diseases in the Tropics. By H. C. Trowell, M.D., F.R.C.P. Second edition. Baillière's Medical Manuals for Africans. (Pp. 219; illustrated. 4s.) London: Baillière, Tindall and Cox. 1945.

The second edition of this handbook incorporates several important additions and changes necessitated by recent advances of knowledge since the first edition was published. The chief of these concern the use of the sulphonamide drugs, while a new chapter on diets and malnutrition has been added. The object of the book, according to the author, is to acquaint African nursing orderlies and dressers with those aspects of medical and surgical disease which must be understood for nursing to become intelligent. He has largely succeeded in this endeavour, producing a small concise book, clearly written, and covering most of the simpler and more practical aspects of disease as encountered by the dresser in tropical Africa. It is more than a pity, therefore, that a number of errors and loosely expressed ideas have been allowed to spoil the work. For example, heart disease is stated often to produce pain under the praecordium—an erroneous idea which, if disseminated to patients, may result in much mistaken distress; the gonococcus is stated to be peculiar in that it can only produce inflammation in the urethra, conjunctiva, and joints, though it must be admitted the author later discusses gonococcal cervicitis and salpingitis; the ambiguous abbreviation S.T. instead of the clearer M.T. is used to designate malignant tertian malaria; in discussing the treatment of malaria, mepacrine is mentioned only, as it were, incidentally and is dismissed in less than two and a half lines; typhus is not mentioned at all; and relapsing fever is said to be transmitted by the bite of the louse. Though we realize that a book of this nature should not be overburdened with detail, it is desirable that what is written for the education of primitive students should be balanced, accurate, and precise.

ADULT TUBERCULOSIS

Pulmonary Tuberculosis in the Adult: Its Fundamental Aspects. By Max Pinner, M.D. (Pp. 580; illustrated. $7.50.) Springfield: Charles C. Thomas. 1945.

The author of this book states in his preface that he has not attempted to write a textbook, his aim being to create understanding rather than to impart knowledge. Prof. Max Pinner has achieved this object so successfully that it is difficult to do justice to his work within the confines of a review. The task of the reviewer must therefore be to encourage others to read the book for themselves.

The early chapters are concerned chiefly with the pathology and pathogenesis of phthisis. Taking the tubercle bacillus as the starting-point, the reader is shown, in turn, the micro-organism itself, its effect upon the body tissues, the reactions it produces, both local and general, and finally the nature and uses of tuberculin. Thence he proceeds to a discussion of the factors which determine the development of clinical tuberculosis; the vexed question of the relative importance of endogenous and exogenous factors in reinfection is skilfully and fairly expounded, but the author shows that it is of less practical consequence than the problem of the causal factors which prepare the soil for the seed. After some wise comments on the classification of tuberculosis, and the proper function of classifications, Prof. Pinner goes on to a systematic description of the whole course of pulmonary tuberculosis, from the primary complex, through the incipient stages of reinfection, to the established chronic disease. This account is illustrated by reproductions of *x*-ray pictures with comparable photographs of necropsy material and photomicrographs. An excellent description of tracheal and bronchial tuberculosis is also included. The later chapters deal with the practical problems of the diagnosis and treatment of tuberculosis. Here again we are never allowed to lose sight of the wood for the trees; our field of vision is extended by fascinating discussions of the physiology of respiration and of the principles upon which treatment is, or should be, based. The brief descriptions of various forms of treatment, including all types of collapse therapy, are admirably balanced, modern, and comprehensive. The book concludes with an evaluation of the results of treatment and a discussion of the epidemiology of phthisis.

This is largely a work of collation and assessment. From a vast knowledge of the literature the author has marshalled, weighed, and set out the facts, never losing sight of his aim, which is to present a picture of pulmonary tuberculosis as a whole, rational and consistent within itself. He does not claim to have added anything new to our knowledge of the disease, and yet the unified conception which he has set forth may seem new to many workers in tuberculosis. Preoccupation with some particular aspect or problem so often destroys the sense of proportion, and perspective is restored by this clear presentation of the established facts which must form the basis of any useful discussion. Mention must also be made of the bibliography, which is noteworthy both for its completeness and for its mode of presentation. At the end of each chapter there is not only a list of the key papers referring to the subject, but also a short review of each article quoted, with notes on its scope and value.

Good books about tuberculosis are not common, and, in spite of his modest claims, Prof. Pinner has added another to our store. Everyone who is engaged in tuberculosis work will enjoy reading and rereading this book, and it is for them that it was written.

NEW SUPPLEMENT TO B.P.C.

Seventh Supplement to the British Pharmaceutical Codex, 1934. Additions and Amendments to Parts I and III, with Cumulative Index. (Pp. 133. 7s. 6d.) London: The Pharmaceutical Press. 1945.

The *B.P.C.*, like the *British Pharmacopoeia*, has been busy in public service during the war giving birth to a family of Supplements. The young of the *Codex* are now seven in number, and the latest addition should be a favourite with a great many.

It is curious that the *Pharmacopoeia* does not put its pride in its pocket and follow the *Codex* in making itself a really useful book by including a section on actions and uses and also a list of proprietary names with their non-proprietary equivalents. Even the *Codex* is rather bashful about proprietary names, for they are not mentioned in the monograph dealing with the substance. Thus the reader will be completely in the dark concerning cinchocaine unless he happens to stumble on nupercaine in another part of the Supplement, where he discovers that cinchocaine is its non-proprietary name. Alas that we must wait for the day, which will surely come, when the proprietary name will appear unashamed in the monograph!

The members of the Codex Committee certainly stick out their necks, as the Americans say, when they describe actions and uses. They deserve credit for their courage, and a recognition that they have written these paragraphs well. Any attempt, however good, would be easy to criticize. Thus, concerning cyclopropane the *Codex* says: "The chief disadvantage of cyclopropane is that it does not stimulate respiration." What anaesthetic does? Surely the right way to explain the chief disadvantage is to say that concentrations of cyclopropane which give sufficient muscular relaxation are not far removed from concentrations which arrest respiration. In this sense cyclopropane compares very unfavourably with ether.

It is satisfactory to find a section on the treatment of barbiturate poisoning, but a pity that strychnine and nikethamide and the use of amphetamine sulphate to raise the blood pressure are mentioned several lines before the one effective drug in barbiturate poisoning—namely, picrotoxin—is brought into the story. Nor would one guess that pholedrine is superior to amphetamine for raising the blood pressure. However, the proportion of generally acceptable statements is very high and makes the Supplement of great value to the medical practitioner.

Notes on Books

We welcome the appearance of a ninth edition of Sir JAMES PURVES-STEWART'S *Diagnosis of Nervous Diseases* (Edward Arnold; 40s.). As the author relates in the preface, it has been compiled with difficulty during the war, many of the new references and illustrations which it was hoped to incorporate having reached the bottom of the Atlantic. The regional and symptomatic arrangement of matter has always made this work popular with students and practitioners alike, since it is an excellent complement to the more systematic textbooks which deal with the diseases of the nervous system. It is unfortunate that medicine in all its branches is becoming so complex, for it means that even textbooks such as this are growing out of hand, and are becoming too heavy and too long to afford the pleasant reading which earlier editions of this work used to give to the last generation of aspiring neurologists. Still the present generation will find the 880 pages before them well worth perusal, and will discover a wealth of information which is not easily gleaned from any other book.

The Inter-Allied Health Charter Movement began in 1943 under Anglo-Czechoslovak auspices, and it has now published a *Year Book*, 1945 edition, putting on record in a series of articles the efforts of Great Britain and her Allies in Western and Central Europe to further Clause 6 of the Atlantic Charter—the famous clause embodying the hope "that all the men in all the lands may live out their lives in freedom from fear and want." One of the introductory articles is by Dr. Norman A. Sprott, who complains of recommendation "B" of the British Medical Association, which, in connexion with the future of the medical services, declares that the health of the people depends primarily upon certain social and environmental conditions. Dr. Sprott thinks this an inadequate and over-simplified statement, and for his own part he sets out fourteen points as essential to health. These include regulation of size of the population, freedom from serious injury and infestation and infection, right choice of parents, and the means of satisfying certain primitive instincts. Extended in this way the word "health" seems to become meaningless; it might just as well be replaced by the word "life." There is a great deal of interesting information in this book about health movements in other countries, but it would have benefited by better arrangement and some sacrifice of matter. It is issued from the Health Charter Communication Centre, 26, Portland Place, London, W.1, at the price of 10s.

For the use of those wanting to revise their knowledge quickly Dr. R. GORDON COOKE has written *A Summary of Medicine for Nurses* (Faber and Faber; 3s. 6d.). In a hundred pages the author gets out brief notes—from "Addison's Disease" to "Worms." For those who like this sort of synopsis this is a good example of its kind.

A Circular (No. 208/45) has been issued by the Ministry of Health on the disposal of Government-owned equipment held by local authorities in excess of their requirements for the Ministry's Emergency Services. It has now been decided that, owing to difficulties of transport and lack of adequate storage space, the bulk of this surplus equipment (other than food, vehicles, and clothing) should be disposed of locally, and that where arrangements can conveniently be made the goods should be offered to the public through traders. The authority for local disposal of surplus goods provided for, or at the expense of, the Ministry of Health is designed to effect speedy clearance of premises, and the Minister feels that local authorities will welcome the opportunity of making domestic goods available to their inhabitants. The Women's Voluntary Services have agreed to help in this task of disposal wherever they can.

BRITISH MEDICAL JOURNAL

LONDON

SATURDAY DECEMBER 15 1945

THE FREEDOM OF THE PROFESSION

We print in the opening pages of this week's *Journal* a list of principles believed by the Negotiating Committee to be fundamental to the practice of medicine, the Minister of Health's statement in the House of Commons last week, and the comment of the Secretary of the Negotiating Committee. It is hoped that everyone will read the three pronouncements with care. The Negotiating Committee, it may be repeated, is composed of representatives of the British Medical Association, the Royal College of Physicians, the Royal College of Surgeons, the Royal College of Obstetricians and Gynaecologists, the Royal Scottish Medical Corporations, the Society of Medical Officers of Health, and the Medical Women's Federation. It is, therefore, truly representative of the medical profession in this country.

The essence of the principles is the freedom of medical men and women to practise the art and science of medicine according to existing knowledge, informed judgment, professional standards, and the dictate of conscience. The framework of the new National Health Service must allow for the exercise of full professional freedom, or the progress of medicine will be halted and the public will suffer.

THE MINISTER'S FIRST STEPS

The Minister of Health's statement in Parliament last week is by now familiar to readers of the *Journal*, and is recorded in full in this week's issue (p. 834). Although the Minister, Mr. Aneurin Bevan, at the same time stated that the Government had not yet decided upon the proposals for a National Health Service which it will submit to Parliament, his considered pronouncement last week is clearly linked up with these proposals. In reply to a question he summarized them when he said, "What I have done is to inform doctors that it is highly improbable that I will permit the sale and purchase of practices." The former Minister of Health, Mr. Willink, called the Government's statement "vague and menacing." He also observed that most of Mr. Bevan's colleagues in the Government agreed that the matter was "one of great complication and not essential to the introduction of the National Health Service. To this Mr. Bevan rejoined that he had every reason to believe that the announcement would be received with great satisfaction by most doctors. If the Minister is basing this assertion on the results of the B.M.A. questionary, it should be pointed out that the analysis of replies from those most directly concerned—namely, general practitioners—showed that exactly half were for and half against the sale and purchase of publicly remunerated practices.

It is important to distinguish between the sale and purchase of publicly remunerated practices and the sale and purchase of practices consisting of patients outside any public scheme. The Minister intends, it seems, to make the buying and selling of the former type of practice impossible. It should be stressed that the promise of compensation covers all capital values that would be directly affected by legislation, and that a man, for example, in a wholly private practice proposing to retire at the introduction of the new service would receive compensation from the Government. If the Minister's sole wish is to make it easier for a young man without means to enter practice, and if he does not intend to interfere with a way of professional life which has evolved on a mutually co-operative basis between doctor and patient and doctor and doctor, then the medical profession would be willing to work out with him ways and means of doing this. But a careful reading of the second item of the Minister's statement (see page 834) suggests that the question of the buying and selling of practices is linked in his mind with the distribution of doctors. To put it more bluntly, the Government intends to buy existing practices so that it can direct medical labour. That is to say, if a young man wishes to succeed his father or join with colleagues in practice in a district where he has grown up and which he knows and where he is known—and the hereditary element is strong in British professional life—he may, by *force majeure*, be translated to another place where he has no native ties or interests. Will this give the public a good doctor and a doctor who is happy in his conditions of work?

If it be granted that there is maldistribution of doctors, is the Minister clear in his own mind about the causes of this? Does he, for example, believe that there is unemployment in the medical profession, or under-employment? The finger of scorn is often pointed at Bournemouth, but Bournemouth and other places like it are to a large extent convalescent homes for invalids. There are probably as many sick people in Bournemouth as there are in Rhondda. The trouble with Rhondda, as the Minister has every reason to know, has not been under-doctoring but unemployment. Anyone with an intimate knowledge of the medical profession knows that there are few men in practice who do not do a full day's work or more, and usually seven days in the week. Doctors are distributed unevenly because there are not enough to go round, and one remedy is not arbitrary direction but an expansion of medical schools and the recruitment into them of increasing numbers of men and women fitted to become medical practitioners. If the argument may be carried a little further we would suggest that the reason why there are not enough doctors is the gross underpayment of publicly remunerated doctors since the introduction of the National Health Insurance Act. The medical profession has its own proposals for improving the distribution of doctors. It is noteworthy that the Minister has suggested a narrow solution of the problem before even hearing the views of the profession on it. Is his desire to direct stronger than the desire to discover the facts of the case?

The practice of medicine demands high qualities of character, an intelligent mind, and a resourceful nature. If the country wants a profession stocked with men having these attributes it will be wise not to produce conditions which will be antipathetic to them. The present Minister of Health is notorious for the freedom with which he uses his speech, and he would therefore, we may believe, welcome an equal freedom of approach on the part of the profession. The profession recognizes that Mr. Bevan has a real interest in the task to which he has set his hand, and a genuine wish to work with the men who are going to provide the service. He has himself said that the new health service cannot be run by men who are discontented or have a sense of grievance. The real difficulty felt by medical men who are not partisan Socialists—and they comprise the majority of the profession—is that they see themselves being called on to fashion a service in co-operation with a Government which has rigid doctrinaire views on the ordering of society. If the Government does not recognize this fact and has not the strength of mind to model the new service on the basis of fact and not theory, then the evolution of medical practice may turn out to be retrograde. Before the medical profession can give a considered opinion on the whole matter it must know what the whole matter is. At the moment it knows no more than what the Minister said last week. But it has read the writing on the wall, and does not pretend to like it.

POST-WAR VIENNA

A White Paper[1] dealing with conditions in Germany from December, 1918, to March, 1919, was published early in 1919; later in the same year the results of a full investigation conducted by Prof. E. H. Starling were published as a White Paper.[2] It is a sign of a decay in the attitude of Governments to governed during the last quarter of a century that no official reports on conditions on the Continent have appeared so far and have been refused by the Government; that official information has been given only in answer to critics in Parliament; that we have had to depend for information on journalists who might well be giving truthful but unbalanced accounts. We must therefore welcome such reports as those of Bastanie and his colleagues[3] on conditions in Belgium (though before this appeared there had been great changes) and that of Magnus Pyke which appears in this number of the *Journal* at page 839.

Comment on the failure to issue any rations for a month after the capture of Vienna, and on the gross inadequacy of rations from June to September, would be superfluous. What most concerns us now is that the Allied Council has since September agreed to try to provide the normal consumer with 1,550 calories daily. This 1,550 standard has been mentioned frequently in the lay press as the minimum needed to prevent continuous degeneration. Dr. Pyke now writes of 1,600 calories; we believe that this is the first time that such a low standard has been suggested by anyone with a claim to knowledge of nutrition. Where did this standard originate? What justification is there for it? In occupied countries rations supplied less; but, as may be seen from Brull's report[4] on conditions in Liège, people got far more of rationed foods such as bread than the regulations allowed. In the last war German rations supplied much less; Loewy's survey[5] (made in April, 1917) shows that people were actually eating about 1,600 calories per head (2,000 per unit) and were getting more than their allowances of rationed foods. Nevertheless there was a progressive decline in health. According to *Food Consumption Levels in the United States, Canada, and the United Kingdom*,[6] " in early 1941 . . . supplies fell to an average of less than 2,700 calories per head per day, and, although rationing was well established, there were indications of impaired health and working efficiency. General experience tends to show that, while the current United Kingdom supply level is adequate, the slightly lower level in 1941 was less than adequate, though some allowance must be made for the rapidity with which consumption levels fell in 1940–1. In other words, the present supply level of about 2,800 calories per head per day is, for the United Kingdom, about marginal." This was 2,700 calories " going into consumption "; the actual food eaten was equivalent to about 2,450 calories. Any impairment of health and efficiency was more probably due to causes other than lack of calories. But we cannot pose a standard of 2,500 calories for ourselves and 1,600 for others. Unemployed in Britain consumed about 2,200 calories a head.[7] Five-year-old children in English industrial towns get, on an average, 2,100 calories.[8] It is reasonable to take as the rock bottom the 2,000 calories proposed by the military authorities as the minimum daily requirement needed to prevent disease and unrest.

Vienna is at any time particularly ill situated for getting food in addition to rations; still more so when armies of occupation are taking any supplies from the country districts. Even in a part of the city which contained large areas of allotment and was situated near the outskirts the calories added amounted to only about 300. Presumably the Allied Council does not intend that the Viennese should add to their 1,550 calories by the irregular methods practised in the occupied countries during the war. The standards for vitamins A and C suggested by Dr. Pyke are much higher; certainly many people in this country have subsisted for a long time on less than 25 mg. of ascorbic acid. But, with no issue of milk to children over 6 years old, the intake of calcium by older children will remain inadequate unless more chalk is added to the flour in Vienna than is added to ours, for 1 lb. of our fortified bread supplies only about 0.26 g. of calcium. Dr. Pyke gives records of heights and weights of children in two schools from June, 1942, when rationing in Germany was already severe. These heights and weights compare favourably with those found in London in 1938,[9] while in 1920 heights and weights in Vienna[10] were much lower than in London in 1905–12. It appears that the special allowances for children in Vienna during the war were adequate, and that even during the worst period of this year the boys got enough to maintain their weights; the girls, who according to Pyke's survey ate less, had lost weight during the year. But if supplies are not increased we must expect a decline similar to that after the last war.

The main problem, then, is to provide calories, and calories can be provided as wheat. Two years ago, at a time when the amounts that would be needed for relief were grossly underestimated, there were some 30 million tons of wheat available. But the International Wheat Council reported in September of this year that "the present estimate of world's import requirements for the year ending July 31, 1946, exceed by a substantial margin the present supplies available for export during that period from Argentina, Canada, Australia, and the United States." On Dec. 7 Sir Ben Smith said in the House of Commons that "one million six hundred thousand tons of wheat were required in the British zone alone, and it was a physical impossibility, because of the world shortage, to supply that." Has all that grain been used up in feeding livestock and making commercial alcohol? If there are the stocks, transport is needed to bring them across the Atlantic and distribute them on land. Was Sir Arthur Salter correct when he said that transport is available? We want a White Paper that will give a full account of conditions on the Continent and of the stocks and transport that can be used for relief.

The sufferings of Vienna have a place in British medicine, for it was there that Dr. Harriette Chick and her colleagues made the classical studies that established the importance of vitamins in human nutrition. The original intention was to study hunger oedema, which was prevalent in 1918; but by July, 1919, few cases could be found. The number of cases in the first weeks of October, 1945, was from 200 to 300. Famine oedema is still a mystery. Why does oedema appear in some cases when the serum proteins are not reduced? Why do the serum proteins fall in some cases and not in others? Could not a team from Britain carry out the investigation which was intended at the end of the last war? In Dr. Chick's report[11] there is a photograph of twins, Ida and Johann Potharany; it appeared in a paper by Chick and Dalyell[12] and has been reproduced several times since then. Both Ida and Johann had had rickets and scurvy: Ida, who had been treated with cod-liver oil, was plump and well grown; Johann had not, and remained a wizened misery. When we compare the reports about children's food in England and Vienna that have appeared within a month we feel that these little figures may be regarded as symbolic of the children in the two countries.

WHOSE LOAF?

In January of this year a Conference was convened by the Ministries of Food and Health and other Departments to discuss the composition of post-war flour and bread. The Conference met six times, and appointed two technical subcommittees to consider special points. Under the chairmanship of Lord Horder one subcommittee reported on the minimum quantities of nutrients to be prescribed in regulations dealing with flour. The second, under the chairmanship of Mr. C. A. Loombe, Director of Cereal Products in the Ministry of Food, looked into the question of regulations covering the content of nutrients in flour. Briefly, the Conference recommends that flour should contain not less than certain minimum quantities of the three "token" nutrients—vitamin B_1, nicotinic acid, and iron—the minima per 100 grammes of flour being, in milligrammes, 0.24 of vitamin B_1, 1.60 of nicotinic acid, and 1.65 of iron. It is stated that these minima can be supplied in the present 80% extraction flour, and recommended that for the time being this should be continued. A further recommendation of the Conference is that before the remaining period of control ends certain difficulties discussed should be studied.

Of the six items needing investigation, four of them refer to reinforcement with the "token" nutrients. In the last paragraph but one of the report of the Conference[1] it is stated that the Government, in the light of further studies, will have to decide whether "it will be both practicable and in the national interest to prescribe, or alternatively to permit, the manufacture and sale of low-extraction flour which has been reinforced by added vitamins."

When the wheat has finally been separated from the chaff, is this country going to have the millers' loaf or the doctors' loaf? That is the question a reading of the report provokes. The millers are concerned about the public taste for flour in various shapes, about safeguarding the position of country millers, and about the business morals of millers. Mr. Loombe's subcommittee "came to the conclusion that a regulation prescribing a minimum extraction rate could not be enforced after the present control of the milling industry ceases." To secure adherence to a prescribed minimum rate of extraction would, it believes, be possible only under a comprehensive system of Government control such as exists at the moment. Again, it is stated that flour milled to a specified minimum extraction rate could be imported only "provided the Governments of the exporting countries were prepared to agree to take the necessary action to ensure that the millers produced for export only flour so milled." Before the war about 10% of the flour consumed in Great Britain was imported from Canada and Australia in the form of flour.

If enforcement of regulations is impracticable, then reinforcement with vitamins is the remedy proposed. This is a sorry conclusion to arrive at, and one, we are glad to see, that is not accepted by "the official scientific and medical members of the Conference." These members "hold strongly the view that flour should not only have the prescribed minimum quantities of the specified nutrients but that those minima should be retained in the flour from the wheat berry in the process of milling." and it is stressed by them that the majority of nutritionists in this country are agreed about the advantage of natural over reinforced foods.

Bread is the staple of the average man's diet. The first civilization was made possible by the fact that wheat grew naturally in the Nile valley. For approximately 6,000 years man's taste was not offended by the whole wheat grain. So once more may we appeal to the millers and the bakers to join in with scientists and doctors in persuading the people of this country to return to a civilized habit. It is wonderful what propaganda will do.

PREFRONTAL LEUCOTOMY

The introduction of prefrontal leucotomy, or lobotomy, nearly ten years ago opened a curious but promising chapter in psychiatry. Whatever speculative afterthoughts are evoked to explain the effects, the measure still belongs to the realm of the empirical. It is not unfair to state that in leucotomy one destroys cerebral tissue of uncertain anatomy and of unknown function for the relief of disorders of obscure nature and pathology. That the operation proves effective in many cases of chronic mental illness is not to be denied, even though—perhaps because—the picture of an organic brain defect replaces that of an obstinate psychosis. We may quote the restrained comments of such experienced "psychosurgeons" as Freeman and Watts,[1] who write: "Above all we do not speak of recovery, since in undergoing prefrontal lobotomy a patient may exchange one psychologic deviation for another. It comes down to a question of which deviation interferes less with his social adjustment. If a patient can take care of himself after operation we are satisfied with the results." The authors are, of course, discussing schizophrenics, in which only two-fifths may be expected to show good results, as opposed to two-thirds of depressive cases and four-fifths of obsessional neurotics.[2]

There are many steps yet to be taken before leucotomy can become a scientific rather than an experimental measure. Some less drastic attack upon the frontal lobes may perhaps produce the same beneficial results. In leucotomy we have an opportunity of neuro-anatomical and physiological research which might well be exploited by the British school of psychiatry. What is the least common factor to be observed in order to achieve results? What is the precise anatomy, and what the exact function of the associational, projectional, and commissural fibres which are sacrificed? Kindwall and Cleveland[3] say that the purpose of prefrontal leucotomy is to cut "the association pathways connecting the prefrontal lobe with the remaining ipsilateral hemisphere and, to an indeterminate degree, the contralateral hemisphere." But Freeman and Watts believe that the effects of leucotomy are due to severance of the fronto-thalamic tracts. Do retrograde degenerative changes actually occur in the dorsomedial nucleus after leucotomy, as has been stated? Further post-mortem studies are required, and much more work on the lines of that of Earl Walker. Understanding of the nature of restitution of cerebral function after brain injuries is largely *terra incognita*, but such statements as "lobotomy tends to produce extraversion, and perhaps its anatomical and physiological significance lies in that realm where correlation between the ectomorphic physical type and the cerebrotonic temperament exist," means just nothing at all. Neurologists and psychiatrists have before them the lesson of the Wagner-Jauregg treatment of general paresis. Empirical in its conception, it was found to work; but malaria, as such, was not the beneficial agent, and now in artificial, rather than natural, fever therapy we begin to witness an understandable and not unscientific measure.

OUTPUT OF CORTICAL HORMONE

Although the presence of a hormone (or hormones) in the cortex of the suprarenal has been clear since active cortical extracts were first prepared, there has been no evidence to indicate in what circumstances the hormone is liberated in the blood. Until recently knowledge of hormone liberation has been confined to the liberation of adrenaline when the splanchnic nerves are stimulated, and of insulin when there is a rise of blood sugar. Verney has lately demonstrated that painful stimuli give rise to an output of one of the pituitary posterior lobe hormones, and now Dr. Marthe Vogt[1] has devised a method of studying the release of hormone from the suprarenal cortex. Her method has been to collect blood directly from the suprarenal vein, to separate the plasma, and to test it by injecting it into young rats after adrenalectomy. If young rats so prepared are exposed to low temperature (2–4° C.) they die in 5 or 6 hours; if they receive injections of cortical hormone at intervals of 1½ hours they live longer, and their survival time is proportional to the amount of cortical hormone given at each injection. This method, applied to groups of young rats, enables a quantitative estimate to be made of the cortical hormone present in a sample of blood taken from the suprarenal vein.

Dr. Vogt was able to determine the presence of cortical hormone in the suprarenal vein of the dog, the cat, the goat, the rabbit, and the pig. She was unable to find detectable amounts in arterial blood or in blood taken from the right side of the heart. The average output of hormone from the dog's suprarenal was very large when compared with the amount present in commercial preparations. One well-known preparation contains the activity of 75 grammes of gland in 1 c.cm. Comparison with this preparation showed that the average daily output of hormone from the suprarenal glands of a small-size dog (10 kg.) is equivalent to 230 c.cm. of commercial extract. The output was found to be of the same order in all species examined when calculated per unit of body weight; there was variation from about half to three times the mean figure (given above).

Dr. Vogt[2] has also shown that adrenaline, when infused slowly into a vein (in amounts which occur in the body in physiological conditions), causes an immediate and prolonged increase in the secretion of the cortical hormone. The normal output increases several times. This effect is not due to changes in the rate of blood flow through the gland or to changes in blood pressure, nor is it an indirect effect exerted by way of the pituitary body. This finding is clearly one of great importance. There have been several indications that the cortical hormone plays a part in conditions of stress; we now see that adrenaline, which serves many functions in an emergency, can call forth an increased supply of the cortical hormone, perhaps to accelerate the formation of carbohydrate from protein, and for other purposes still undefined. Stimulation of the splanchnic nerves was likewise found to cause an increase in cortical secretion.

In a third paper[3] Dr. Vogt has made other observations She has found that injections of adrenaline into young rats, repeated 3 times daily for 8 days, cause an accumulation of fatty material in the cortex, and that if the injections are continued for 24 days the storage becomes greater still and is accompanied by a significant increase in suprarenal weight. These changes do not occur in the absence of the pituitary. Now suprarenal hypertrophy is also brought on by the implantation of tablets of hexoestrol, but this hypertrophy differs entirely from that produced by adrenaline, since it is accompanied by a complete disappearance of fat from the cortex, and the cells are seen to have swollen cytoplasm and nuclei. Rats treated with hexoestrol die more quickly than normal rats when the adrenals are removed, which suggests that hexoestrol administration results in a diminution of the amount of cortical hormone produced in the gland. The increased amount of lipoid material produced by adrenaline therefore probably represents an increased store of the hormone.

SUBACUTE DEGENERATION OF THE BRAIN IN PERNICIOUS ANAEMIA

Subacute combined degeneration of the spinal cord is the best-known neurological complication in pernicious anaemia. The name is somewhat clumsy and inaccurate, and for this reason Kinnier Wilson,[1] following the lead of French authors, suggested that it be replaced by "neuro-anaemia," although he was fully aware of the fact that there is probably no direct causal relation between the anaemia and the degeneration of the spinal cord. Subacute combined degeneration may precede disease of the blood, and may even be found in conditions such as cage paralysis of monkeys, in which anaemia is not known to occur. The present theory is that "neuro-anaemia" is due to a deficiency closely allied to but not identical with that of the anti-anaemic principle. There is no evidence for any of the known vitamins being involved in the pathogenesis of the condition.

Subacute combined degeneration usually ends at the level of the crossing of the pyramids in the medulla. It is not generally known that in a number of cases of macrocytic anaemia the cerebral white matter may be affected by a similar patchy demyelination. In a recent paper Adams and Kubik,[2] reviewing earlier reports in the literature and adding personal investigations, have proposed the name "subacute degeneration of the brain," thus emphasizing the pathological and pathogenic similarity with the lesion in the spinal cord. It is interesting to note that in cage paralysis of monkeys the lesion of the spinal cord is usually complicated by a very extensive patchy demyelination of the cerebral white matter. The occurrence of such demyelination has been held responsible for mental changes in pernicious anaemia. According to Bremer[3] psychopathic manifestations are found in about 20% and psychotic symptoms in 7 to 8% of patients suffering from pernicious anaemia, the frequent terminal confusional states being excluded. The psychotic manifestations are usually of the acute confusional type with hallucinations and delusions, but chronic depressive and paranoid syndromes have been reported. However, the demyelination of the cerebral white matter is not the only cause of mental symptoms. Some of the psychoses and psychoneuroses observed in the course of pernicious anaemia are merely exacerbations or recurrences of previous mental abnormality. Anoxia resulting from the impaired condition of the red blood cells is another possible source which may particularly account for the terminal psychotic manifestations. Moreover, evidence grows that vitamin-B deficiency, though not directly involved in the pathogenesis of subacute degeneration, may complicate pernicious anaemia. In pellagra, widespread chromatolysis of large nerve cells of the type known as retrograde degeneration is a constant histological finding, and this nerve-cell change has been reported in a number of cases of pernicious anaemia. It has also been shown (Campbell and Biggart[4] and Meyer[5]) that the Wernicke syndrome may arise in the course of pernicious anaemia. This syndrome is now recognized[6] as being caused by deficiency of vitamin B_1.

The fact that pernicious anaemia may be complicated by vitamin-B deficiency is naturally of therapeutic importance. Moreover, it may at last resolve the old controversy whether or not the lesion of the spinal cord in pernicious anaemia is accompanied by a degeneration of peripheral nerves.

ULSTER MEDICAL WAR RECORD

The number of medical graduates of the Queen's University of Belfast who served in the war is 660, so far as can be ascertained. Of these the names of 420 were dealt with by the Northern Ireland Medical War Committee, and it is considered certain that more than 240 others practising in various parts of the Empire volunteered for service without notifying the university. Some 50 medical students also volunteered. Graduates and undergraduates killed in action or dying on active service numbered 33, and 5 others are missing. Decorations were bestowed on 55, who included four recipients of the D.S.O. and 17 of the Military Cross, while 27 others were mentioned in dispatches. Four members of Queen Alexandra's Imperial Military Nursing Service lost their lives. When it is remembered that conscription was never applied to Northern Ireland, it is claimed for these figures that they constitute a noteworthy record of voluntary service. The Belfast Medical School thus sustains a long and honourable tradition, which began at the time of Trafalgar, and in the 1914-18 war gave some famous names to military medicine.

NUFFIELD CHAIR OF CHILD HEALTH

The Nuffield Trust has once more performed a highly valuable service in adding yet another extension to the always incomplete structure of medicine by founding a Chair of Child Health in the University of London. The details of this were given in the *Journal* of Sept. 23, 1944 (p. 410).

The next stage in this work has now been completed by the appointment to the chair of Dr. Alan Moncrieff—an appointment which will ensure that the work will be carried out with energy and thoroughness, and with every prospect that solid contributions to knowledge in this branch of medicine will come out of the institute in the years to come. Dr. Moncrieff is still of an age when it is permissible to describe him as a young man, and those who know of his enormous industry and of his versatility in so many fields of medicine will hope for great things from the new institute, which he now comes to preside over at the age of 44. Since 1934 he has been on the staff of the Middlesex Hospital and the Hospital for Sick Children at Great Ormond Street. Before this he studied the problems of respiratory failure and asphyxia of the newborn in Germany while holding a Rockefeller Medical Fellowship; and before this, again, had prosecuted his paediatric studies in France. For many years now he has served as Editor of the *Archives of Disease in Childhood*, published by the B.M.A., and has won distinction in other fields of medical journalism.

Reports of Societies

STETHOSCOPE *versus* X RAYS

A debate on the stethoscope *versus* *x* rays took place in the Section of Medicine of the Royal Society of Medicine on Nov. 27, with Dr. Geoffrey Evans in the chair.

Dr. James Maxwell said that recent advances in medicine had put an increasing strain on the unfortunate medical student. A pruning process was needed to give the student the opportunity of digesting more recent and fundamental knowledge. In past years emphasis in diagnosis had been laid on physical examination and signs. Nowadays these were not nearly enough. Unfortunately other aids were not used and many doctors never learned to interpret them. The student of twenty years ago had been little better off, in his knowledge of chest signs, than his predecessor a century earlier. Many doctors now practising made the false assumption that if they found no physical signs in the chest there was nothing wrong. The absence of physical signs did not exclude tuberculosis or early bronchial carcinoma, both of which were curable if detected before physical signs were present, but few teachers had the courage to teach this for fear of stultifying their elaborate instruction of physical signs. On the other hand, radiology was not taught to any great extent, and there were not enough radiologists to examine every suspicious chest case. Students should be taught the *x*-ray appearance of the normal chest and its variations before they went into the wards, in their second year of anatomy and physiology. They should be shown lateral and oblique as well as antero-posterior views, and then, entering the wards with this fundamental knowledge, they could start to look at abnormal appearances. At the same time, physical examination must not be abandoned and *x* rays would not replace it. Often an *x*-ray film would reveal a lesion which physical examination would miss, and sometimes the converse was true. Students should be made to listen to every variety of sound until they knew them perfectly, and then, when they knew that they had to have the patient radiographed, and knew what the *x*-ray image meant, the accuracy of chest diagnosis would be immeasurably improved. Examiners should be familiar with the interpretation of *x*-ray films. A practitioner who did not insist on an *x*-ray examination of a suspicious chest, especially after haemoptysis, might be sued for negligence.

Possibilities and Limitations of X Rays

Dr. Peter Kerley said that the rash statement was made from time to time that the stethoscope was obsolete; no experienced radiologist would agree with that. When an experienced physician found physical signs he himself was surprised if he found nothing on an adequate (he emphasized the word "adequate") *x*-ray film. In a hundred years the stethoscope had not altered fundamentally; it had reached its limits, and those limits, even in skilled hands, were so narrow that radiography was indispensable. Deficiencies in radiology were due in part to lack of skill and in part to ignorance of living anatomy and physiology. The old phrase that an *x*-ray film was a representation of shadows was wrong. No physicist to-day would agree with the word "shadows." The *x*-ray image was a collective picture of structures of different densities, and these could be identified almost as precisely as on the dissecting table. One of the main causes of error was reliance on a single antero-posterior view. For a proper interpretation not only views in three directions but also tomography were essential. Important technical points were the smallness of the focal spot on the anode and the speed of the exposure. Before long a spot of only 1/250th mm. would probably be available. Condenser units would replace transformers for speed, and their wave form would give finer detail. Magnification with detail would be much increased during the next ten years. The radiologist's battle was not with his medical and surgical colleagues, but with hospital and financial administrators who were aghast at a proposed expenditure that was derisory compared with the cost to the country of half a million registered tuberculous persons.

Radiography was, however, hopelessly beaten by the stethoscope in the diagnosis of heart conditions. But many advances had been made by cardiologists using the screen entirely, and they would get better results if they also took pictures with rotating anode tubes. Contrast media for angiography would soon be made completely safe, and then radiologists would be able to show the chambers of the heart and the pulmonary circulation with comparative ease. Given the staff, the equipment, and the necessary funds, the stethoscope might be put in danger of obsolescence.

Lessened Importance of the Stethoscope

Dr. Geoffrey Marshall said that there was no reason why they should do without either instrument, but if he had to take one without the other it would be the *x* rays every time. He would be very sorry, however, not to be able to examine his patient in addition, and the stethoscope might be very useful as an adjunct to radiography. By means of the stethoscope he could find out whether a wrong name had been placed on the *x*-ray film or the wrong side of the body indicated. It would be just as reasonable to talk of the stethoscope *versus* history-taking; they wanted everything they could get. *X*-ray films could be misleading and much more difficult of interpretation than was at first supposed. Dr. Maxwell's plea that students should be taught how to use *x*-ray films of the chest could not be too strongly supported. Would *x* rays always give an indication of cavitation in the lung? A straight view would very often fail to do so. Radiologists were very often ready to admit with all due modesty that they could not tell what was the significance of an abnormal appearance. The more experience they gained the more difficult did these cases seem to be. The *x*-ray picture was far from revealing a complete pathology. Students should be told the limitations of *x* rays as well as of physical examination. The stethoscope had certainly descended from its throne; it was not of such vast importance to them now as it used to be, but it still lingered in the imagination of the patient, and medical men—even those who specialized in chest diseases—when they themselves had chest trouble wanted the colleague examining them to listen to the chest. It was difficult to avoid going through the gesture—it was not much more than that—of trying to hear vague mysterious sounds, when something quite definite could be seen on the *x*-ray film. He wished to reinforce Dr. Kerley's plea for multiple views and especially for tomographs.

Dr. L. G. Blair said he shuddered at the notion that every man should be his own radiologist. After he himself had reported on chests for a year he became extremely confident—and extremely dangerous. He hoped that he was now less dangerous, and certainly he was much less confident. He did not feel that either students or doctors, if the latter were not doing much chest work, could be taught enough about chest radiology to be practically useful. The answer to the problem was more team work, as in the various thoracic units, in which the radiologist should probably take a leading part. Radiology was supremely important on three great groups: where there were no physical signs, where physical signs were present but of little use without radiology, and where diagnosis could be made with certainty on physical signs but the extent and distribution of the disease could be shown only by *x* rays. Against these three groups there were a comparatively few conditions in which physical signs were present but radiology gave no evidence of disease—for example, non-obstructive lesions of the bronchial tree, bronchitis, and some cases of bronchiectasis. The activity of a lesion, particularly a tuberculous one, was a clinical matter. The present order of examination—history, physical examination, and radiography—should be retained. It should be remembered and taught that in the vast majority of chest conditions the history was of the greatest importance, radiology came next, and physical signs were often only an aid, though at times a very valuable one, to the correct interpretation of films.

A Jig-saw Puzzle

Dr. Maurice Davidson said he was accustomed to teach students that a carefully taken history was often worth 60% or more of the value of an opinion. The teacher should emphasize that all his examinations could show only the gross underlying anatomical differences in the viscera, and only when these were correlated with the information supplied by the pathologist and the bacteriologist and with the knowledge gained previously in the post-mortem room (not so frequently in these days), and all the bits of the jig-saw were placed together, could one reach a really satisfactory conclusion.

Dr. PHILIP ELLMAN said he taught that radioscopy and radiography were important aspects—indeed, a part—of the clinical examination. A clinician chiefly concerned with chest diseases was the most suitable person to do radioscopy, and if he had an expert team he might study the film and consult with his radiological colleagues in a difficult case. He thought it was wrong to look at the film first; this should follow the history, good palpation, good percussion, and good auscultation. Accessory means such as bronchoscopy and bronchography must be included.

Dr. A. L. JACOBS was of opinion that the worst failure was in the frequent neglect of the general practitioner to order an *x*-ray examination of a test case. As a rough general rule, any doctor who saw a patient with a cough and sputum persisting for more than a short time should insist on an *x*-ray examination of the chest. Without team work between the physician, the radiologist, and the general practitioner the position would not be improved. In organizing specialist services throughout the country, particular attention should be paid to areas in which general practitioners were isolated from large hospitals.

Dr. W. M. CROFTON declared that early tuberculosis of the lung could be revealed only by a proper tuberculin test as well as by the stethoscope. The treatment of tuberculosis was in a very sorry state, and he believed that mass *x* rays had been positively dangerous in condemning sound persons to invalidism.

Dr. C. ALLAN BIRCH recalled that almost a hundred years ago Thomas Addison of Guy's had read a paper condemning the stethoscope. Instruments passed through three stages: extravagant claims, severe criticism, general use until ousted by a better method. The stethoscope was now in the third stage. Clinicians, however, should continue to use the stethoscope because patients expected to see it, and a patient not satisfied was not completely treated. Mr. L. C. OLIVER said that the stethoscope, though apparently the chain of office of the physician, was of more practical value to the surgeon, particularly in the diagnosis of acute abdominal disease.

Dr. JOSEPH SMART said that he would be very sorry to see the physical signs and stethoscope abandoned. With an accurate history and careful examination of the chest it was often possible to reach a reasonably accurate diagnosis, or at any rate to differentiate between two or three conditions. The position of the mediastinum was vitally important in chest work and an extremely valuable physical sign. A less expert radiologist might, by introducing a slight rotation, confuse the clinician badly, and then a clinical examination might help much. He himself would be content if students and general practitioners were trained to recognize a normal *x*-ray appearance and to pass on the abnormal ones for closer investigation. He added that in children physical signs of pulmonary disease were notoriously scanty and reliance had to be placed almost entirely on radiological appearances.

THE TRAINING OF DIETITIANS

A conference of the Nutrition Society on the "Training, Qualifications, and Function of Dietitians" was held on Nov. 17 at the London School of Hygiene and Tropical Medicine.

Prof. J. R. MARRACK, who presided during the morning session, in the absence of Sir Jack Drummond, said that dietitians in close contact with the actual consumers of food were ideally placed to report to those ultimately responsible on the physical and psychological effects of food policy. They must guard against the propagation of fads, such as unjustified prejudices against certain foodstuffs; the prevalence of "acidosis" in children, for example, might be ascribed to the dietetic prejudices of their nurses. Dietitians must avoid the over-simplification of ideas typical of the late Victorian era. The current popular classification of foods into "builders" and "warmers" must not be accepted too literally. A diet consisting entirely of bread was inadequate for the nutrition of experimental animals, but could be made adequate by adding yeast. Bread contained only poor-quality protein, which was supplemented by the good protein of yeast. Unfortunately, however, the same experiment might be done in reverse. Rats which failed to thrive on a diet of yeast might be successfully nourished by the addition of bread. Dietitians should be trained, therefore, to keep a sense of perspective. They should know when it was legitimate to compromise between dietetic ideals and the exigencies of the larder and kitchen, and when nutritional requirements were so vital as to permit no compromise.

Prof. S. J. COWELL discussed conflicting opinions as to what the word "dietitian" implied. Dietitians were responsible for the feeding of human beings and, as in the nursing profession, some basic training was essential. There must be some authority, such as the British Dietetic Association, to approve courses of instruction and to lay down the standards to be satisfied by individuals before they could be granted official status. The dietitian must have knowledge of the science of nutrition, based on the elements of chemistry, physics, and physiology, and must also have adequate practical experience in the conversion of raw foodstuffs into adequate meals for healthy or sick people. She must be adept in the purchase and storage of food, and the arrangement and care of kitchen equipment. She must be able to guide and instruct the numerous cooks and other personnel responsible for large-scale catering. Dietitians were often employed now in schools, canteens, and other institutions, but many were still concerned with the feeding of both patients and staff in hospitals. Those engaged in feeding healthy persons might also have to advise occasionally on the feeding of the sick. There was much to be said for retaining a period in hospital in the vocational training of all dietitians, but this should not be the only practical experience required.

The British Dietetic Association

Miss R. PYBUS spoke unofficially on the British Dietetic Association and its role in co-ordinating the training of dietitians. This organization was formed in 1936, and had about 300 full members working in this country. A subcommittee inspected any training centre wishing to be recognized by the association, and visited hospital departments and other institutions where practical experience was offered. Many hospitals and other bodies regarded membership of the association as an essential qualification. Full members were encouraged to register with the Board of Registration of Medical Auxiliaries, although this did not mean that they intended to confine their activities to feeding the sick. The essential academic qualification for dietitians was a diploma in dietetics, which might be gained at King's College of Social Science, the Glasgow and West of Scotland College of Domestic Science, the Royal Infirmary of Edinburgh, or the Royal College of Nursing. The 18-months course included both theoretical and practical instruction in cookery, elementary anatomy and biology, bacteriology, nutrition, budgeting, kitchen administration, catering, infant feeding, diet in disease, and the medical aspects of disease treated by diet. Practical work in hospital during the final six months gave experience in the calculation, preparation, and service of special diets. Before taking a diploma course students had to have a university degree in pure household or domestic science, the State registration in nursing, a teacher's diploma in domestic science, or an institutional management diploma.

Miss M. C. BROATCH emphasized the slow development of dietetic training in this country as compared with America. By 1925 the American Dietetic Society was a powerful body, and was disappointed with an attendance of only 2,000 members at its annual conference! English dietitians were employed only in the special-diet kitchens of hospitals, whereas in America they were in charge of all the catering in many large hospitals. When the need for qualified dietitians became apparent in this country the first five women sent out to America for training all took charge later of special-diet kitchens in their respective hospitals. Greater opportunities for dietetic activities might be expected in the future in the new health services, in welfare centres, in prenatal and postnatal clinics, and in schools and colleges. Miss Broatch did not agree with certain hospital matrons who thought nursing experience essential for dietitians. Training in large-scale catering, however, could not entirely replace instruction in the special-diet kitchen, where the facilities for constant individual teaching by a qualified dietitian were excellent.

Lieut.-Col. A. N. CHILDS said that greater efficiency resulted if the dietitian was in charge of a separate department responsible to the registrar of the hospital rather than to the matron. Dietitians in America were also employed in commercial organizations. In 1927 one firm tried the experiment of giving details of food values against all the items on their menu. College graduates in white coats went round giving customers scientific advice as to what they should eat. Unfortunately the mental strain proved too much for the customers, and led to the first introduction into America of the *table d'hôte* system.

Mr. A. L. BACHARACH said that hospital dietitians were the people who had succeeded in putting dietetics "on the map." It was a more open question, however, whether the present medical bias indicated the right line for the future development of the profession. Nutrition was a social rather than a medical problem. More healthy people had to be fed in schools, in industrial canteens, and at home than sick people.

Nutrition in Social Medicine

Dr. F. C. BROCKINGTON stressed the importance of nutrition in schemes of social medicine. With the prospect of a four-year university degree course in dietetics it was important to find for dietitians positions worthy of their training. There seemed to be insufficient scope for the full-time employment of a dietitian in a school meals scheme or in a small hospital. It was encouraging that the health departments of local authorities should have it in their power to create more important posts. The dietitian might be called on to provide dietary health propaganda for the housewife, to give lectures and demonstrations to health visitors and others, to advise hospitals, schools, and institutions, and to plan and supervise dietary surveys. Everyone interested in the proper care of the sick had welcomed the report of the King's Fund on hospital diets. Nevertheless it was unfortunate that the question of feeding the sick should have been given first attention. The balance must be redressed by creating posts from which the entire dietetic field could be surveyed.

Mr. F. LE GROS CLARK said that the Ministry of Education had based its estimates on the assumption that 75% of the average school attendance would obtain midday meals at school. This meant that some 3,300,000 children must be fed on 200 days in the year. Since the school dinner was supposed to provide half the daily requirement of protein, fat, vitamins, and mineral salts, about 30% of the child's yearly requirement of these nutrients would be obtained at school. Under the 146 distinct local education authorities in England and Wales there should be careers for 500 to 700 suitably qualified women. The organizer of school meals should have a sound knowledge of "conservative" methods of cookery by which vitamins and other labile nutrients might be preserved. Experience of large-scale cooking was most important. The school meal must not be a poor imitation of the delights of the home cuisine, but should be endowed with subtleties and attractions that were all its own. Local authorities would find it worth while to attract women of high administrative qualities. This would be possible only if the salary and status corresponded with those of other careers involving a comparable measure of responsibility.

Miss F. C. R. BROWN discussed the work of dietitians in industry. The Institutional Management Association recently published a report on the employment of women in large-scale catering and household administration. A standardized basic two-years training should include the management of canteens, bookkeeping, storekeeping, stocktaking, and industrial relationships. During a third year practical experience should be gained as a junior member of the staff of some organization approved by the training authorities. The number of canteens in this country had increased during the last six years from about 500 to over 18,000. Much higher salaries were earned by highly placed industrial caterers than were paid to hospital dietitians.

Hospital Dietitians

Miss J. I. MILLS said that a hospital of 700 to 1,000 beds required several dietitians. The catering officer, or food supervisor, was responsible for general administration, staff control, and for the purchase, storage, and distribution of foodstuffs. It was still a matter of opinion whether this officer should be a qualified dietitian or an executive with commercial experience of large-scale catering. The assistant catering officer had control of menu planning and the supervision of the preparation and service of meals. Her special responsibility was to supervise the feeding of the hospital staff, and she probably needed two further dietitians to supervise the feeding of the patients in the general and private wards, respectively. The dietitian in charge of the dietetic department was responsible for the planning, calculation, and preparation of special diets, for maintaining close contact with patients, nurses, and doctors, and for the supervision and instruction of the nurses and student dietitians in diet-kitchen cookery. Centralization had solved many difficulties in the control of staff and supplies, but the ideal arrangement for the distribution of cooked food from the kitchen to the wards had not yet been evolved. In the newly built Southern Hospital in Stockholm the problem had been tackled by decentralization. Instead of one kitchen attempting to serve 1,200 patients, twelve smaller kitchens, each under its own dietitian, each served 100 patients.

Miss WASHINGTON surmised that if all the attributes of scientific knowledge, domestic skill, and strength of character required by the various speakers were to be combined in one person, that person would be more than human. Sound training must be supplemented by long years of hard experience, and trained dietitians should be reserved for large hospitals or for key positions in the public health services. Dr. T. MOORE said a knowledge of nutrition was only one of the many and varied qualifications which were expected of dietitians, who appeared to be exclusively of the female sex. The advanced state of organization already reached in teaching dietetics in this country contrasted very favourably with our almost complete lack of facilities for the teaching of nutrition from a more scientific aspect. Dr. L. W. MAPSON drew attention to the weak link between the research laboratories, where knowledge of nutrition was accumulated and co-ordinated, and the various organizations concerned with teaching dietetics. University chairs in nutrition were urgently required.

Summarizing the day's proceedings, Dr. H. E. MAGEE, who presided over the afternoon session, said that while access to advice on nutritional questions was essential for those running canteens or school meals, these activities should not require the services of qualified dietitians, who should be employed in hospitals or in the public health services. It was important not to overload the syllabus, and to know where to stop in teaching the basic sciences, any of which could obviously absorb the whole time of the student if taught in full detail. Hospital experience should be an essential feature in the training of all dietitians. The aim should be to give a sound basic training, after which the student could branch out and specialize according to her own inclinations. Finally he stressed the importance of nutrition in public health training, and the need for collecting information on dietary habits by visits to the homes of the people.

During the conference it was announced that the new address of the British Dietetic Association is 342, Abbey House, Victoria Street, S.W.1. (Abbey 4909.)

An exhibition dealing with penicillin is being held in the Palais de la Découverte, the equivalent in Paris of the Science Museum, South Kensington, and a part of the University of Paris. It illustrates the discovery and early development of penicillin in Britain, and also the contributions of the U.S.A. and France. The British material, which has been assembled by the British Council, includes: a collection of penicillin cultures and bacteriological preparations from St. Mary's Hospital, London; a set of photographs of the Penicillin Research Unit, Oxford, showing the results obtained during the Italian Campaign, lent by Lady Florey; coloured photographs, showing the treatment of gunshot wounds, lent by the Medical Research Council; and reprints from various sources on clinical results obtained with penicillin. The exhibition will continue for about three months, and it is hoped that Sir Alexander Fleming and Sir Howard Florey will visit it and give lectures.

Correspondence

Buying and Selling of Practices

SIR,—Most of the arguments against dealing in practices are too obvious to merit further emphasis, except I think insufficient stress has been laid upon the enormous hardship imposed upon the young and often penurious practitioner. The details concerning loans and life insurance have been pointed out, though the need for fairly heavy cover against other risks such as sickness and accident has not been mentioned. But what is not generally appreciated is that these are not isolated items but arrive as the last straw in a pile of costs incidental to the taking over of a practice.

The event may well coincide with family responsibilities, and in any case the whole cost of furnishing and running a house has to be met. Very often the purchase of a house is necessary, and even if a fairly good mortgage is obtained this is just another gem in the necklace of millstones to be worn for many a year by the unfortunate young practitioner. Car and other equipment add to the load of debt; even accountant's and solicitor's costs can be a burden in the absence of any remaining capital. And it must not be forgotten that for about half the first year little or nothing is received from the practice unless capital has also been found to buy the retiring practitioner's book debts. Even then the aspiring medico is only in a position to begin his gamble with all the factors that make or mar a successful doctor, including many—such as "squatters"—that are completely beyond his control. And all this may arise out of the fact that he was prepared to undergo the most arduous training to enable him to serve his generation in one of its greatest needs. If not deterred altogether by the prospect he may proceed to inquire why he must still surmount such enormous financial obstacles before he can finally get in touch with those who await his skilled attention. And, of course, that question does not become easier to answer with an increasing number of public contract patients.

Under any 100% scheme, dealing in practices would be most anomalous, and, as pointed out in your leading article (Dec. 1, p. 770), we must now in any case face the thorny problems attendant upon abolition of the custom. "By dint of hard work and professional competence" most of us have maintained, if not increased, our incomes. But so far as the goodwill is concerned many of us would gladly amalgamate that to the general prestige of the profession for the simple return of all the cash we handed to the fellow who left his reputation behind. However, we in turn have been left to obtain our compensation from those who come after, and cannot very well deny that whoever buys us out is customarily entitled to our individual rights, even if we are thenceforth employed as assistants in our own practices. Herein lies the problem, as your leading article intimates. Can doctors forgo a commercial interest in the transfer of their practices without having to choose between a dead loss on the one hand and being split into individual Government properties on the other, and without rendering the process of transfer liable to even greater abuses than it is under the existing system?

Insoluble as the problem may seem at first sight, I think the answer to such questions might well prove to be in the affirmative. And I venture to suggest that one solution might be found in the transference of individual ownership of goodwill into the hands of the profession as a whole. Instead of transferring our goodwill to public ownership by accepting Government money, I would suggest that the profession as a whole buys out the goodwill of its constituents and then rents it out again to individual doctors.

The profession would have to elect a body whose function would be to raise the initial capital and purchase with it all practices, either at once or as their owners retire. It would have a committee corresponding to the British Medical Bureau whose function would be to see that transfers, retirements, acquisitions, or creations of practices were all arranged to the greatest mutual advantage. For this and other services, together with the enjoyment of all the present rights arising out of purchase, all practitioners would pay a rent amounting to a fixed percentage of their earnings, subject to a minimum. This rent could easily be collected at source, especially in a 100% National Health Service, and should rank as a practice-expense for income-tax purposes. The percentage of the earnings taken as rent for each practice would not need to be unduly high to cover the cost of the capital represented in the goodwill, and might be varied according to the type of practice. The percentage rent would, of course, depend upon the terms obtained by the profession from the financial interests loaning it the capital to liquidate doctors' individual ownership of goodwill. The loan would probably not be a permanent one, in which case the day would eventually arrive when the profession would retain ownership of its goodwill and require no more from individual doctors than payment of a small practice rent to cover the cost of administration.

The Government might be prepared to loan the profession the required capital rather than resort to other measures to prevent the sale of practices. They would certainly be likely to prefer a loan to the advancement of capital. However, the funds could probably be provided most satisfactorily by those insurance companies who will miss the large "rake-off" they have enjoyed out of both the National Health Insurance and loans for purchases of medical practices. Their interest in the venture would be considerably heightened if they also provided a complete pension insurance scheme for the whole profession. The percentage rate for each practice would have to be a little higher if such things as pensions and free locumtenents for sickness were part of the benefits to be derived from it.

Although we might even be more favourably compensated for our present outlay under such a scheme than by any the Government may have in mind, we and our immediate successors would have to realize that our practice rent, for many years to come, not only would include the redemption of our debt but would carry with it the redemption of our practices for all time from the status of publicly owned utilities. Moreover, our young successors with more wit than money might also rejoice in a professional status and great security without at any time having to shoulder a burden of debt out of all proportion to their income.—I am, etc.,

Eye, Suffolk. J. SHACKLETON BAILEY.

Medical Future of the Colonies

SIR,—The leading article in the *Journal* of Nov. 17 and the letter from Mr. R. Ogier Ward (Dec. 1, p. 781) are both opportune. More and better teaching centres are needed in the Colonies. All must be familiar with the present difficulties of accommodating those who have graduated at colonial medical centres and who wish to study as postgraduates in Britain. At present it seems that first-class medical education needs to be taken to them rather than they be encouraged to come to this country, where already postgraduate facilities are strained to the utmost, and where there exists the perennial question of colour.

In your leader the suggestion that there should be a Director-General with a panel of consultants seems an excellent one. I note that advisers in obstetrics and paediatrics have been omitted. Those who have worked in a colony appreciate the appalling wastage of maternal and child life, and if any subjects need proper emphasis these are they.

The teaching centres in Britain should be more elastic and should encourage exchange between their teachers and those of the colonial medical centres. The Dutch had this system of exchange before the war. I well remember entertaining at Hong Kong Prof. de Snoo, professor of obstetrics at Utrecht University, who was on his way on an exchange visit for a year to Batavia University. Later he told me what an education it had been for him working in such a strange *milieu* as an obstetric hospital in the Tropics. I would suggest that facilities should be given for not only the chiefs but also their juniors to participate in such an exchange.—I am, etc.,

London, W.1. W. C. W. NIXON.

Disordered Liver Function in Rheumatoid Arthritis

SIR,—The interesting paper by Drs. Frances Gardner, Alice Stewart, and F. O. MacCallum on induced jaundice in rheumatoid arthritis (Nov. 17, p. 677) discusses fully the possible bearing of bilirubin in the blood on the disease, but except for reference to variation in the blood proteins, which may be due to disordered liver function and give rise to the alteration in the erythrocyte sedimentation rate in rheumatoid arthritis, the possible influence of other disturbances of hepatic function is not considered. I believe that the explanation of the effect of jaundice in these cases is to be sought in some such disturbance, of which the jaundice is simply an index. Hench, in his work on the problem, called attention to the fact that remissions similar to those occurring in jaundice complicating arthritis also occur in pregnancy. There is a common factor in both conditions which may deserve investigation in any future research. Morris and Peden (*Quart. J. Med.*, 1937, **6**, No. 22, 211) have reviewed very fully the variations in plasma phosphatase in disease, and note that it is much increased in many froms of jaundice and at the sime time mention that Cayla and Fabre have found it much increased in pregnancy.

The coincidence may be of no importance, but on the other hand it seems worthy of further investigation. The occurrence of osteoporosis of the articular ends of the bones in rheumatoid arthritis, due presumably to lowered osteoblastic activity, suggests that there may be a lowered phosphatase, and both jaundice and pregnancy tending to raise it may beneficially affect the progress of the disease. I hope to be able to have some observations carried out on the plasma phosphatase level in active rheumatoid arthritis, but must leave the other possible aspects of the problem to research workers with better facilities.—I am, etc.,

Buxton. C. W. BUCKLEY.

The Discharging Lesion in Neurology

SIR,—Dr. F. A. Pickworth (Dec. 1, p. 784) will find answers to some of his questions when my paper is published in full, and I anticipate that it will appear in the forthcoming number of *Brain*. Meanwhile I may say that I am in full or partial agreement with many of the statements in his letter. I would point out, however, that even if it could be established (as he asserts) that "faulty integration of nerve impulses is the cause of untoward clinical symptoms," faulty integration would not account for the discharges arising at a site of injury in an isolated nerve in the laboratory.—I am, etc.,

London, W.1. J. PURDON MARTIN.

Descent of the Testis

SIR,—This problem, as Wing Cmdr. A. W. Badenoch (Nov. 3, p. 601) states, is one in which "the fancies are prolific." There are, however, three separate problems to be distinguished, and to summarize them as a "search for a lower temperature" is to use a teleological explanation in an unjustifiable manner. The three problems involved are: (1) the actual forces operating on the testes in any individual mammal during its development; (2) the function subserved by this phenomenon; and (3) the phylogenetic origin.

With regard to the first problem, a temperature difference could not enter into the system of forces operating on the gland unless there were *both* a tropism tending towards a movement to a cooler region *and* a temperature gradient existing along the whole route of descent, so that it could affect the gland in its abdominal site and initiate movement. Such a temperature gradient does not exist along this path. We do know that endocrine factors affect descent in some way. In animals which have a rutting season, and in which the testes descend at this season (rat and guinea-pig), there is an intermittent secretion of the male hormone, whilst in man it is continuous. But it is not justifiable to conclude that the secretion of hormone initiates the descent in any individual.

It has been suggested that the function subserved by the descent is the need for a lowered temperature for spermatogenesis. In criticism of this view the following points may be made:

1. Spermatogenesis takes place throughout the majority of the Invertebrata and the lower Vertebrata at a varying temperature range. It is difficult to see why in such a well-established process a few degrees should suddenly become so important. In the case of most birds the process is carried out at a temperature higher than that of the mammals. With regard to the cause of bird migration, most authorities are agreed that it is a search for fresh vegetation, and the fauna thereon, to be found in temperate zones. It might also be pointed out that spermatogenesis and egg incubation take place at the temperature of the bird—that is, in some cases over 100° C., whatever the surrounding temperature.
2. In the figures given for the human subjects, in the article cited above, the average lowering of temperature in the scrotal sac was only 2.2° C. These data were obtained with passive anaesthetized subjects, and it is to be questioned whether in the active subject the temperature *inside* the testis, where spermatogenesis takes place, is indeed lower than in the peritoneum.
3. Any lowering of the temperature in this region must be carried out by radiation and sweating. Such could not be achieved in tropical conditions in those animals in which sweat glands do not occur.
4. The rest of the experimental evidence, and the facts of cryptorchidism, could as well be explained on the following theory. In those animals in which the extra-abdominal position has been established for *any other* function, spermatogenesis has become secondarily adapted to a lowered temperature, if this does occur. It perhaps cannot now take place at a higher temperature.

This brings us to consider any other possible function which an extra-abdominal position could serve, and this can only be considered in relation to the possible phylogenetic origin of the phenomenon. The problem does not in its evolutionary aspect primarily concern man. He merely inherited it as part of his lowly origin. The extra-abdominal position of the testes appears to have arisen at least twice among the mammals: (*a*) in the Marsupalia, although the scrotal sac is not developed here; (*b*) in the true placental mammals. Darwin has suggested that "as a general principle, of all the causes leading to an external difference between the sexes, the principle of sexual selection was the strongest." The descent of the testis during the rutting season in some rodents suggests that this might be a means of sexual attraction in animals having few other visible sexual differences. In the lower mammals, which are mainly nocturnal in habit, the intra-abdominal position is retained. In the Proboscoidea and Cetacea, where the internal position is probably secondary, the thick covering of these animals would make the genitalia inconspicuous in any case. The whole phenomenon may have arisen as a "chance" mutation which gave the possessors a survival value in mating, and upon which natural selection could work.—I am, etc.,

King's College, Newcastle-upon-Tyne. MARY A. WOOD, Ph.D.

Pituitary Stimulation by Light

SIR,—The annotation on the work of Benoit and Ott on pituitary stimulation by light (Nov. 17, p. 695) has been of great interest to medical ornithologists and one hopes to others. Will you allow me as an amateur ornithologist to make some comment on the concluding sentences of the article.

It has been known for nearly a century that the gonads of most of our wild birds are in a state of profound though temporary involution, except during the breeding season. It is not only the fancy of the young bird that turns to thoughts of love in the spring but the mature bird is also thus affected. Yet, in spite of profound depression of the germinal epithelium of both sexes, which makes unseasonal reproduction impossible, some sexual display occurs in a number of species in the autumn. Two British game birds—the wild duck (mallard) and the black grouse—are good examples. In the mallard mating display leading to normal but sterile treading is regular in the autumn on the Continent. I may add from personal observations that this also applies to the English mallard, as might indeed be expected. Autumnal display of male black-game was, I think, first recorded by A. Chapman in Northumbrian birds, and has since been confirmed by observers in several other areas in Britain. The interesting feature here is that display, communal and very elaborate, repeats the "normal" spring display, except for the immediate preludes to mating. In autumn it arouses no interest in the hens.

We may presume in such cases that a *change* of illumination, increase or decrease, is the effective stimulus for gonadotrophic hormone secretion. Also, in the black-game it appears that the cock is more sensitive to such changes than the grey hen. In view of the experiments reported in your article, which indicate tissue penetration by light as apart from direct retinal stimulation, it is conceivable that the supraorbital wattle of bare skin, found only in the males, has some bearing on this differential behaviour of the sexes in autumn.—I am, etc.,

Physiology Department, Guy's Hospital, S.E.1. E. O. HÖHN.

Non-specific Mesenteric Lymphadenitis

SIR,—Mr. Ian Aird (Nov. 17, p. 680) has done a great service in reminding the profession that non-specific mesenteric adenitis is an extremely common condition and frequently missed. I would endorse most of what he says, but I would differ from him on the following points.

1. *Pathology.*—I regard these glands as bearing the same relation to the appendix as the tonsillar glands to the tonsil; in cases where the tonsillar glands are enlarged the tonsils usually show no gross abnormality, but tonsillectomy is generally followed by subsidence of the glandular enlargement. If, however, the vitality of tonsillar glands is impaired by allowing a chronic infection to persist, the tubercle bacillus is liable sooner or later to settle in them; this sequence is commonly seen in mesenteric adenitis, where a string of glands is encountered, one or more of them showing caseation or calcification. For this reason I prefer the term "ileo-caecal" to "non-specific" lymphadenitis.

2. *Symptoms and Signs.*—The cases fall into two main groups: (a) Acute:—The surgeon is usually asked to operate on an "acute appendix." I would agree with Mr. Aird's description, except that I would go further in the matter of temperature and say that "acute appendicitis" with a temperature of 103–104° immediately raises the suspicion that we are dealing with adenitis rather than appendicitis, although such a temperature by no means rules out the latter. And pain in the right iliac fossa on palpation of the left does sometimes occur. (*b*) Chronic or, preferably, recurrent:—Ileo-colic adenitis is the commonest lesion present in the children who are so often sent up to out-patient departments with a diagnosis of "chronic" or "subacute appendicitis." In these the enlarged glands are frequently palpable, but not necessarily tender.

3. *Prognosis.*—As Mr. Aird says, this is a self-limiting disease, the attacks generally ceasing at puberty or in adolescence. It can usually, however, be cut short by appendicectomy.

4. *Differential Diagnosis.*—(*a*) Acute cases:—A history of previous attacks, although suggestive, can, of course, sometimes be elicited in cases of acute appendicitis. An important point Mr. Aird does not mention is that a clean tongue is the rule in acute ileo-colic adenitis but rare in acute appendicitis. The pre-operative differentiation, although satisfying, is mainly academic because in the first condition appendicectomy is beneficial and in the second imperative; in other words, the treatment is the same but the urgency is not. It is much more important that the surgeon should be honest and not try and convince himself that the appendix, the appearance of which in these cases varies from completely normal to somewhat injected, is a "true bill." The really inflamed appendix is practically always turgid with oedema, and even in "true appendicular colic" the inflamed glands, which are the real cause of the pain, will often be found. (*b*) From chronic appendicitis:—I believe that this does not exist in childhood and that enlarged glands can always be found *if looked for* (unless the child has been operated on for an innocuous belly-ache). (*c*) From tuberculous adenitis:—Caseous or calcified glands are obvious at operation, and so are the large masses of tabes mesenterica. Apart from these the presence of tubercle in the commonly encountered glands is impossible to verify without biopsy, which is unnecessary and therefore meddlesome. (*d*) From intussusception:—Ileo-colic adenitis occurring in infants can mimic this very closely. I have seen the diagnosis turn on the presence of blood on the examining rectal finger; only unfortunately it turned out that the blood had been produced by splitting of the anal mucosa by the large forefinger of an eminent paediatrician. However, appendicectomy was followed by subsidence of the grossly enlarged glands.

5. *Treatment.*—The condition will probably subside in time, but if appendicectomy will allow the glands to subside before the tubercle bacillus gets at them it should be performed in all cases. The parents should, however, be warned that the pain is due to the glands and not directly to the appendix, and that, though in the majority of cases the child will have no further trouble, one or even a few more attacks may occur while the inflammation is resolving. Even with obvious tubercle in one or more glands there is no need to mollycoddle the children as tuberculous; take out their appendixes and let them lead a normal healthy life.

The story of my own son illustrates some of the foregoing points. From the age of 6 he had periodic vague abdominal discomfort with no physical signs whatever, but enough to raise in my mind the suspicion of ileo-colic adenitis, particularly when he told me that while away at school he had had one or two short attacks of colic. This year, at the age of 10, he produced a severe attack while we were on holiday in Cornwall, with tenderness and rigidity in the right iliac fossa on direct and left-sided palpation, but with a clean tongue. The attack subsided, so I had him operated on when we returned home. He had a string of enlarged glands, the lowest one calcified, and a normal appendix. He has had one or two lessening attacks since then, but I confidently expect him to be quite well in six months, with no treatment beyond the extra milk obtainable after any major operation.—I am, etc.,

Guildford. G. H. STEELE.

SIR,—Mr. Ian Aird (Nov. 17, p. 680) says that non-specific mesenteric lymphadenitis has found no general acceptance as one of the commonest causes of acute abdominal pain in children. As long ago as 1921 the late Dr. Brennemann of Chicago read a paper before the American Pediatric Society on this subject. This paper was subsequently published in the *Amer. J. Dis. Child.* (1921, **22**, 493), and the condition has since been widely known, as Brennemann's syndrome, as a clinical entity that is recognized by most paediatricians.

Mr. Aird says that the differential diagnosis from tuberculous mesenteric adenitis is not always easy, and that in cases of doubt "it serves better the interest of the patient and community to regard the condition as non-specific unless there is clear evidence of tuberculosis elsewhere." Surely this is one of the conditions where a tuberculin test is essential in differentiation: a negative Mantoux will exclude tuberculous adenitis.

In the diagnosis of appendicitis the rectal examination is often helpful, but no mention is made of this in Mr. Aird's otherwise comprehensive paper.

Mention is made of lymphadenitis and infectious mononucleosis in differential diagnosis, but there is a much commoner condition—abdominal allergy—to which no reference is made. Here the blood count usually shows a leucopenia with an eosinophilia, and this, together with a careful history, will aid in arriving at a correct diagnosis.—I am, etc.,

Warwick. WILFRID F. GAISFORD.

Recurrence of Infective Hepatitis

SIR,—Current articles in books and journals do not give a clear lead on the question of frequency of recurrences in infective hepatitis. The condition is known to relapse frequently usually between the third and sixth weeks, and is very variable in its severity. That true second attacks take place is hinted at rather than stated dogmatically. I have come across no mention of repeated attacks.

Recently I have been looking after a patient, a soldier aged 33 years. I have inspected clinical records of an illness suffered in November, 1942, notified as true infective hepatitis, and characterized by three weeks of dyspepsia, four days' anorexia and vomit, followed by icterus for eight weeks, palpable liver, bile in the urine for four weeks, and yielding to a low-fat, high-carbohydrate diet. This illness took place in the Middle East. At the time the incidence of epidemic infective hepatitis in the man's unit was high, and there is little reason to suppose that he did not indeed suffer from that condition. Specific note was made of the absence of malaria parasites, negative W.R., absence of exposure to arsenic or other toxic substance. His last inoculation previous to the onset of jaundice was routine T.A.B. and tetanus toxoid five months before. He had had no blood transfusions or serum products.

He remained fit and on duty until September, 1945, when he returned from Italy on leave by air. The day after arrival he felt anorexia and headache and vomited. There had been no jaundice in his unit recently and he attributed his malaise to the effects of the flight. Three days later he was admitted to hospital with icterus, bile in the urine, palpable liver, and complained of headache, anorexia, and tender abdomen after vomiting. The jaundice was of moderate severity, and after eight weeks he was discharged bile-free, liver not palpable, icterus slight. The treatment was by rest and diet only, and lotio calamin. for pruritus. Again the blood W.R. was negative, no malaria parasites found, no toxic substances or transfusions or serum preparations given. In February, 1945, he had T.A.B., and tetanus toxoid inoculations, typhus vaccine in

September, 1945. On convalescence the E.S.R. was 10 mm./1 hour (corrected), no anaemia, serum bilirubin 1.0 mg. per 100 c.cm., icteric index 15 units, and the urine contained a trace of urobilin. The oral hippuric acid excretion test gave an assessment of liver function at 65% of normal. There seems little doubt that this was a fresh infection of infective hepatitis.

It would be interesting to learn of the frequency of this occurrence and the ultimate prognosis with reference to cirrhosis of the liver.—I am, etc.,

JAS. D. P. GRAHAM,
Capt., R.A.M.C.

Military Hospital, Drymen.

Breast-feeding to Time-table

SIR,—In her letter on breast-feeding (Nov. 24, p. 744) I feel that Dr. Anne Toms lays herself open to criticism. I agree with her that the psychological aspect is important, but I disagree with her proposed remedy.

It is not necessary that everybody's arrangements should have to be upset for the sake of a rigid adherence to the infant's schedule. It is of importance that the baby should be fed regularly; if there must be an irregularity, let it be a regular one—i.e., let the mother begin all the feeds a quarter or a half hour earlier than usual. This will still allow the normal interval, which is essential for successful lactation and for the development of a healthy, thriving baby.

If the baby is howling and half-satisfied, the solution is surely not to feed the baby at irregular intervals. The result in my opinion would be the very state of affairs Dr. Toms is anxious to avoid. It would be wiser to investigate the mother's technique in feeding. Does she use both breasts? Does she empty the breasts after the feed? Does she feed the baby regularly? Does she look after "wind"? What is the state of the bowels? There are many aspects of the problem and they all demand consideration before a solution is suggested.

I think the average husband would be only too glad to give up a mere fifteen minutes to allow the baby to be properly fed. He would be a poor type indeed who would not make that small sacrifice. I fear that, by adopting the suggestions advised by Dr. Toms of making the baby fit the family time-table and not the family fit the baby's schedule, the baby's chances are being jeopardized and it would be a case of "out of the frying-pan into the fire."—I am, etc.,

Rugby. JOHN L. FARMER.

Incidence of Breast Abscess

SIR,—I have to thank Dr. Phillis Dingle for the interest shown in two papers of mine dealing with the incidence of breast abscess, and I should like to make one or two comments on her letter (Nov. 24, p. 744).

In my investigation into the incidence of mastitis the area concerned was relatively small and circumscribed—a town of 43,000 inhabitants—so that it was possible to follow up all cases for at least six months after delivery. All mothers in the town are visited by health visitors in the ordinary course of their duties, and during the period of the investigation any case of mastitis occurring in the district was reported. Despite this cases were missed, but some were found at child welfare and other clinics. By this means an incidence of suppurative mastitis of 8.9% was reported. At the same time, for the purpose of the vitamin C experiment described, 250 mothers (all but fifteen were hospital deliveries) were closely followed up for six months after delivery, and in only seven instances was it not possible to do this. These mothers were visited and kept under continuous observation for six months, a questionary was completed at the end of this period, and all cases of mastitis were carefully checked and verified. It is submitted that it was because of the intensive and exhaustive follow-up over a prolonged period (nearly half of the cases occurred after the end of the fourth week) that the high incidence was brought to light.

Dr. Dingle states that she made inquiries at clinics and hospitals and from general practitioners, but admits that only half of these replied. I might point out that if in our investigation only half of the mothers had been followed up or had replied to the questionaries, the incidence would presumably have been considerably less.

Finally I should like to mention that no manipulation of any kind—hand expression, expression by pump, or massage—was carried out in the hospital concerned, and ante-natal measures similar to those described by Dr. Dingle were employed.—I am, etc.,

Dundee. ANNIE A. FULTON.

Artificial Pneumothorax Refill

SIR,—I was most grateful for Dr. C. F. Hawkins's views (Nov. 24, p. 742) on local analgesia for pneumothorax refills in criticism of Dr. Alastair Allan's double-channel needle (Nov. 3, p. 607).

I emphatically agree with Dr. Hawkins that local analgesia is to be deprecated, being only necessary until there is an adequate pleural space, which is often present even after the first week. I also have found that patients infinitely prefer to have their refills without "local"; there is no pain (provided the needle is sharp and inserted quickly), and the puncture wound is cleaner and heals more rapidly. On at least one occasion I have given refills normally done by another doctor, and it has happened that the needle has been plunged into the chest before I realized that that particular patient was in the habit of having local analgesia. The patient, instead of being dismayed, has been amazed and gratified that the refill has been devoid of sensation, whereas the raising of an intradermal wheal during local analgesia had been distinctly painful.

I agree also with Dr. Hawkins that the danger of pleural shock is no greater when local analgesia is disregarded. I believe that true pleural shock, though it does exist, is rare and probably occurs only about once in 10.000 pleural punctures. It appears to me to bear no relation to pleural analgesia, but to be connected more with the presence of fear on the part of the patient and allied to the sudden syncope which sometimes occurs after a blow on the larynx or sudden stretching of the anal sphincter. It is usually fatal within a few seconds, and it may be that death takes place from ventricular fibrillation. Cases showing sudden collapse during or after a refill, with coma, convulsions, pallor, and paralysis, are generally due to cerebral air embolism, and though they may be fatal, recovery usually takes place. In this connexion Andosca and Foley (*Amer. Rev. Tuberc.*, Sept., 1945, **52**) have analysed some of the literature on pleural shock and cerebral embolism, and stress, among other things, that routine local analgesia for refills should not be employed on account of the danger of novocain poisoning, which has to be distinguished from cerebral embolism and which is sometimes fatal.

Dr. Allan's new needle appears to me to be cumbersome and, indeed, unnecessary, since the use of the Peter Edwards pneumothorax apparatus with a standard single-bore needle enables the manometer to be retained in circuit before, during, and after the refill.—I am, etc.,

PHILIP M. WARD,
Assistant Tuberculosis Physician.

Swansea.

SIR,—I would like to support Dr. C. F. Hawkins, who in his comment (Nov. 24, p. 742) on Dr. A. Allan's plea for anaesthetization for pneumothorax refills urges the greater humanity of refills given without local anaesthesia. I also find that patients invariably prefer to be refilled without its aid. Dr. Hawkins rightly stresses the need for (1) first ensuring an adequate pleural space, (2) an experienced operator, and (3) sharp needles. The technique he describes is, I think, much the same as that employed at most large refill clinics, and is similar to that used at this hospital for at least twelve years. The point that he raises about the possible increased risk of pleural shock is an important one. A large number of refills are given at this hospital (over 5,000 in 1944), and in the last eleven years I have known only one case of air embolism and no case which would fit the description of "pleural shock."

I personally believe that the majority of the catastrophes reported are due to an unrecognized air embolism, though the less startling episodes are often simply "faints." In skilled hands, I do not believe that the risk of air embolism (or of pleural shock, if such exists) is increased by not using local anaesthesia. Nevertheless, if there is any doubt about the pleural space, anaesthesia provides the test of ability to withdraw air into the syringe from the pleural cavity, and should be used in such cases. Those confident individuals who regard an A.P. refill as a simple and foolproof procedure (and there *are* such people), and who do not take the simple but rigid pre cautions needed to reduce the risk of air embolism, are asking for trouble and sooner or later get it. In training a succession of assistants in pneumothorax work I always stress the danger of air embolism (not pleural shock) as the ever-present risk which can be reduced to negligible proportions by constant vigilance.—I am, etc.,

RAYMOND C. COHEN,
Essex County Hospital, Braintree. Deputy Medical Superintendent.

SIR,—I am in complete agreement with Dr. Alastair Allan when he advocates anaesthetization of the needle tract when giving artificial pneumothorax refills (Nov. 3, p. 607). Given skilfully with a fine needle there is practically no pain, and I have had no complaint with this technique, even from children. My method of introducing the pneumothorax needle is by a rotatory action while maintaining a steady pressure. In this way the skin is easily penetrated and the slight "give" when going through the pleura can be distinctly felt. Thus there is no danger of going too far and entering the lung if it happens to be well expanded.

I was surprised at Dr. C. F. Hawkins's statement that "an adequate pleural space . . . is generally confirmed during the third week" (Nov. 24, p. 742). My experience, now going back over fifteen years, is that whether there is going to be adequate space can be estimated in most cases after the first three refills —i.e., within at least a week of the induction. I am convinced that only by screening the patient after every refill, and sometimes, if felt necessary, before giving the refill, can complete and proper control of the pneumothorax be established and trouble avoided.

Regarding the question of pleural shock, I have never had anything remotely resembling this occur in literally thousands of refills, and I am very doubtful whether there is such an entity.—I am, etc.,

S. D. ROWLANDS,
Tuberculosis Medical Officer and Medical Superintendent.
Whinney House Hospital, Gateshead.

SIR,—Having received A.P. refills, personally, regularly for the last six years, and having given them also for nearly as long, I can whole-heartedly support Dr. C. F. Hawkins in his contention that a refill without anaesthetic, once the A.P. is well established, is infinitely preferable to preliminary local anaesthetization.

Raising of the intradermal wheal can be a most uncomfortable process, and it is surprising how often the "local" fails to anaesthetize the pleura. On the other hand, a Morland needle deftly inserted "in one" is usually painless, and I have had painless refills without anaesthetic with much larger needles of the Saugmann type.

I am not yet sure if I have met true "pleural shock," but I have had several cases with syncope, in some of which there have been definite symptoms of embolism. Without exception these cases had preliminary anaesthetization, but in all the possibility of puncture of the lung with the needle cannot be excluded. All responded immediately to inhalation of amyl nitrite from breaking a capsule. Like Dr. Hawkins I am loath to give a refill unless the manometer is in circuit throughout.—I am, etc.,

"T.B. M.O."

Volvulus of Small Intestine

SIR,—Stimulated by the case history given by Mr. R. Salisbury Woods (Oct. 13, p. 496), I beg to submit the following report of a case of volvulus of the small intestine.

A child aged 9 years was in good health on Aug. 30, 1945. He returned home from an afternoon's play, ate his tea quickly, and shortly afterwards vomited. After vomiting he complained of abdominal pain, which, he said, was not severe; he was put to bed. Later in the evening he vomited several times, and about midnight he vomited some undigested food together with about half a cupful of blood. At 4 a.m. he vomited a small quantity of bright red blood, believed to be about a cupful. The doctor was summoned and he was admitted to hospital at 6 a.m.

On admission his condition was one of profound shock; temperature 97°; pulse 160; blood pressure 45 systolic, diastolic could not be recorded. The tongue was coated. There was central abdominal distension with generalized tenderness, but no visible peristalsis or rigidity. A transfusion of whole blood was set up and allowed to run at a slow drip, and at 10 a.m. the condition was re-assessed after nearly a pint of blood had been given. The patient was then comatose, the signs of shock persisted, the pulse had remained at about 150, and the abdomen was more distended. A diagnosis of intraperitoneal haemorrhage was entertained, but the child was moribund and died at 12 noon.

Necropsy revealed about a pint of blood-stained fluid in the peritoneal cavity. There was a volvulus of the entire small intestine with incipient gangrene extending from a point 2 in. from the duodeno-jejunal flexure to within 4 in. of the ileo-caecal valve. The mesentery had been twisted through 180°, the caecum, which was very mobile, lying in close relation to the duodeno-jejunal flexure. There was marked ecchymosis of the mesentery, the stomach and duodenum contained several ounces of dark altered blood, and the jejunum was distended with altered blood.

Further to the case report of Mr. Salisbury Woods and the letter from Mr. Roberts (Nov. 17, p. 704) it may be remarked that the condition of volvulus of the small intestine receives very scant attention in recent editions of textbooks. In particular Prof. Grey Turner writes (*Modern Operative Surgery*, 3rd ed., 1943, p. 903): "Volvulus of the small intestine is extremely rare; the condition usually involves the whole mass of the small bowel and the exact diagnosis is only made by exploration." Hamilton Bailey (*Emergency Surgery*, 5th ed.) describes only volvulus affecting part of the small intestine —a not unfamiliar sequel to adhesions affecting the small bowel. The interest of this case is chiefly in the initial symptom of haematemesis, and it is reasonable to suppose that had the case presented immediately after the first haematemesis and prior to the development of gross abdominal signs, immediate laparotomy might have been undertaken with success.

I am indebted to Mr. R. Vaughan Payne and Dr. E. Claud Malden for permission to publish this case.—I am, etc.,

BRIAN WEBBER,
King Edward VII Hospital, Windsor. Resident Surgical Officer.

Surgical Catgut

SIR,—Since starting in practice in 1910 I have used the same brand of British catgut until the present time. There has never been sufficient variation in the size or strength of the two chief gauges used—namely, 2 and 6/0 (occasionally 3/0 or 4/0) —to cause any serious worry even in threading the Paterson-eyed needles which I use. Neither has there been any sepsis which could unequivocally be attributed to catgut, and no tetanus. At first I prepared my own by the iodine–spirit method and had it tested, because I did not know the methods used by the different firms and so felt insecure; but to-day this is not the case. Other gauges and eyeless needles have also come into use.

Differences in gauge cannot matter very much. I used to see a well-known London surgeon using No. 4 for his ligatures and leave the ends long when I should have used No. 4/0 or No. 6/0 and had the ends cut short. With some methods of preparation the gut shrinks considerably as it dries while waiting to be used and gauging goes by the board. Strength increases with drying.

Incidentally I do happen to notice a great wastage of gut (about one-third) when the tied ends are of equal length. Without the use of a spool this need not occur; with the use of a spool it seldom occurs, especially if the one-handed knot is employed. A useful spool is a piece of glass tubing 1 in. long by 1/2 in. in diameter, costing less than a penny. Makers could most helpfully adopt this or something similar and include it in the ampoule with advantage to all concerned.—I am, etc.,

London, W.1. G. H. COLT.

Incision for Appendicectomy

SIR,—I read with interest Mr. Alexander Lyall's article on the treatment of acute appendicitis (Nov. 24, p. 719). In describing his choice of incision for the various types of the disease, Mr. Lyall, to my surprise, makes no mention of the oblique muscle-cutting incision of the late Rutherford Morison. This incision, which is strongly advocated by Prof. Grey Turner, is to my mind probably the best approach to the routine "acute case," and especially to an appendix abscess. For a retrocaecal or retrocolic appendix it seems to afford the maximum of accessibility with a minimum of trauma to the adjacent peritoneum. An appendix abscess can be thoroughly evacuated with ease in the majority of cases, the drainage tube being brought out through the posterior end of the incision, where it is well out of harm's way. If the cut muscles are carefully sutured in two or more layers with interrupted catgut there is a negligible risk of post-operative hernia. The incision is unsuitable for females, where disease of the pelvic organs must be excluded, also in recent or recurrent attacks in children, where the McBurney approach causes a minimum of trauma and convalescence is thereby correspondingly shortened.—I am, etc.,

Croydon. J. ROSS MACNEILL.

Therapeutic Effect of Induced Jaundice

SIR,—In the *Journal* of Nov. 17 (p. 677) Dr. Frances Gardner *et al.* quoted my finding that the E.S.R. may become strikingly slower during an attack of infective hepatitis. Dr. E. Muir (Dec. 1, p. 782) appears to assume that this improvement in E.S.R. indicated an improvement in the pulmonary tuberculosis for which my patients were undergoing treatment. I hasten to state that the improvement in E.S.R. was not maintained, and the course of the tuberculous disease was not influenced noticeably, either for the better or for the worse.—I am, etc.,

Cheshire Joint Sanatorium,
Market Drayton. A. CLARK PENMAN.

Prostatic Obstruction

SIR,—May I congratulate Mr. H. Hamilton Stewart on his paper on prostatic obstruction (Nov. 24, p. 724) with his evaluation of the suprapubic and perurethral methods of treatment. To me the different approach to the perurethral method in this country and in America is most striking, for they are almost diametrically opposite. In the States very many surgeons, both experienced and inexperienced, are using the method, and it has been the exception for an American journal of urology not to contain at least one article on it during the past five or six years, whereas in this country the surgeons using the method regularly are few and far between, or so it would appear from the small number of papers on the subject.

This is the more surprising when one has seen the excellent post-operative condition of the patient after the perurethral operation, with his ability to sit out of bed on the first post-operative evening and to walk round the ward on the second day. Also one cannot fail to be impressed by the vast improvement from the patient's point of view in the freedom from pain and absence of a suprapubic wound and drainage tube; and while Harris's method or that more recently published by Wilson Hey (*Brit. J. Surg.*, 1945, **33**, 41) eliminates the drainage tube it cannot eliminate the pain and the resulting partial immobilization of the patient by the suprapubic wound.

With regard to the examination of the patient, I cannot agree with Mr. Stewart that the supine position is the best for bimanual examination of the prostate. In my experience, in the knee-elbow or knee-chest position, particularly if the patient sits back almost on the heels, it is astonishing how easy it is to make the finger touch the hand on the abdominal wall when the bladder is empty, and assessment of the size of the prostate can be formed easily and efficiently except in the very stout. I should have thought that the supine position with the legs in the frog position would inevitably cause some tightening of the abdominal wall.

The two main disadvantages of the perurethral operation are the prolonged period required to acquire the necessary skill and post-operative haemorrhage. Barnes in his book *Endoscopic Prostatic Surgery* states that no surgeon felt proficient until he had treated 100 cases by this route, and personal experience has shown that the speed and efficiency of resection have varied directly with the number of cases treated. I found, for example, that it was not until I had treated about 50 cases that I could remove 40 g. at one sitting, that amount being resected in 30 minutes and the remainder of the operation being occupied by haemostasis. Arising from this point I think Mr. Stewart estimates the size of the normal prostate rather high at 30 to 40 g.; most authors quote it as 20 g., and I have had many cases where the removal of from 10 to 25 g. of tissue has resected the adenomata down to the capsule with abolition of all residual urine.

Post-operative haemorrhage is the complication which necessitates the highly trained nursing staff that Mr. Stewart so rightly insists is essential. A relatively small amount of haemorrhage can cause sufficient clot to block the Foley's catheter, and prevention of this requires much skill and patience on the part of the nursing staff. On the other hand, the recent introduction of "thrombin topical" for instillation into the bladder at the end of the operation has practically removed this complication in most cases. I find now that instead of bladder washouts being performed every 15 minutes for several hours they are performed only every 6 hours, to the great relief of the nursing staff and the added comfort of the patient.—I am, etc.,

Rochdale. A. M. MCMASTER.

Haematuria after Injection of Rectal Haemorrhoids

SIR,—Dr. W. Kevin Barry states (Nov. 10, p. 668) he has never heard of haematuria after varicose veins injection. Personally I have had no case of haematuria after varicose veins injection, but as a point of interest a surgeon recently injected some rectal haemorrhoids and the patient suffered afterwards from profuse haematuria for a while. Cystoscopy was done but no local lesion could be found, and the haematuria cleared up after a week without further treatment or complication.—I am, etc.,

Ely, Cambs. KENNETH HAZELL.

Chronic Undermining Ulceration

SIR,—Mr. Aubrey Leacock, in his interesting paper on a case of chronic undermining ulceration treated with penicillin (Dec. 1, p. 765), states he could not find any reference to this type of ulceration in the English medical press. Mr. Leacock might be interested in the following references: "Ulcerating Granuloma of the Pudenda: Treatment by Zinc Peroxide Paste," H. M. Hanschell, *Brit. J. vener. Dis.*, 1944, **3**, 123; and an abstract in the *British Journal of Dermatology and Syphilis*, 1945, **7–8**, 159, of an article, "Microaerophilic Haemolytic Streptococcus Infection causing Destruction of Nose," by M. J. Costello, *J. Amer. med. Ass.*, 1943, **121**, 36.—I am, etc.,

London, W.1. GEOFFREY DUCKWORTH.

The Harvard System

SIR,—Mr. Alexander Lyall has written such an excellent paper (Nov. 24, p. 719) that it is disappointing to find it marred in two places by defects inherent in the Harvard system of references. The reader unversed in the history of surgery would naturally conclude that John Hilton published his *On Rest and Pain* in 1930, and that Ochsner described his "delayed" treatment in 1934, whereas the correct dates are respectively sixty-eight and twenty-eight years previously.

In spite of your reply to Dr. C. Langton Hewer (Feb. 17, p. 234) I think further protest called for. You stated then that the system gives two pieces of information at once—the name of the author of a statement, observation, or theory, and the date on which these were published. It is evident, however, that the ordinary reader wishing to gain a correct perspective will want to know when these were *first* published, while the research worker or librarian, for easier reference, will prefer the date of the latest edition or article. As in the present instances, these will often be reprints or recapitulatory articles. It seems to me that both cannot be satisfied at once and that this slipshod and cumbersome method of attempting to do so should be abandoned.—I am, etc.,

Salisbury A. DUFF.

Disability not Disablement

SIR,—It is not altogether surprising to learn that the response of the war-injured to the invitation to register for employment as "disabled persons" has been poor. The successful rehabilitation of these men and women depends among other things on the acceptance of the fact that though they have a disability or even disabilities such need not result in disablement. In many cases, with suitable surgical appliances, proper training, and appropriate modifications of the industrial process or machine, the effects of even a substantial disability may be so mitigated as to become, if not negligible, merely a minor handicap. True, it requires courage as a rule to achieve this, but it becomes thoughtless, even cruel, to say then to such persons: "In order to improve your chances of employment you must now register as a 'disabled person.'"

A "register of disability" need carry no such stigma of inefficiency. Firms might well be proud to employ beyond the requirements of the Act numbers of keen men and women with well-compensated disabilities, whereas the employment of a "quota of disabled persons" savours too much of enforced assistance or reluctant charity. We owe it to the men and women concerned to see that the value of this scheme is not jeopardized by the use of inappropriate nomenclature. Clearly it is not only the patient who should learn that "disability" does not spell "disablement."—I am, etc.,

Hill End, St. Albans. W. J. T. Kimber.

Food for Europe

Sir,—We often find ourselves telling patients that their ailments are due to deficient food. Whether this is accurate may be open to question, but it is an undisputed fact that European children are dying of starvation. We as doctors may be unintentionally supporting those who argue that as we have not enough food for ourselves we can send nothing abroad. Good organization would improve food distribution and shopping facilities in England, and make possible the dispatch of desperately needed food to starving people. We entreat doctors to use their influence with their patients in support of this measure of relief.—We are, etc.,

John Elam.
New Barnet. F. Jean Vinter.

The "Stamping" of the Guards

Sir,—Before committing themselves further on "stamping" in the Guards, if they have had no close-up view of the subject, may I suggest that members read *Private in the Guards*, by Stephan Graham, published in 1919. The author was one of the greatest of famous pedestrians, before and after his experiences in the Guards Depot at Caterham. It is very evident that in spite of the rigorous training, stamping, etc., he was very proud of having been a Guardsman.

I served in the 'nineties as battalion medical officer in the Grenadier Guards, and never once, despite our long route-marches, did I meet with a case of varicose troubles or other injury due to the training and plenty of fatigue and stamping. The O.C. never once failed to accept my advice in cases of severe blisters or illness of any kind that would reduce a man's efficiency. Doubtless some rather "lame ducks" got into the Guards in the great rush to become a Guardsman in recent years; it is equally certain that they got weeded out at the depot.

The "smartness" of the Guards is known all the world over, and the rare occurrence of trivial injuries must not obscure the great aim of those who have to turn men into Guardsmen—soldiers obvious half a mile away.—I am, etc.,

Bournemouth. W. Johnson Smyth.

Sir,—May I, a civilian, who has served in two wars as an R.M.O. and A.D.M.S., say that I have always had my advice sought and received with the greatest consideration. Equally I have always recognized that the final decision lies with the commander. Is it, in fact, certain that march fracture is caused by stamping the feet? Is it commoner in the Guards than in other line regiments or even in the corps like the R.A.S.C. and R.A.O.C.? My own experience is limited, but I consider that it is commonly caused by route marches and is as much due to poor muscular tone as to any other factor.

Finally, may I say that I am in cordial agreement with Major E. Grey Turner (Nov. 17, p. 707) in his attitude to this matter. After considerable personal experience I can assure Dr. J. W. Perrott (Dec. 1, p. 786) that a battle "jeopardizes the men's health"; I have never advised that one should be cancelled. Equally a battle can be jeopardized by poor discipline. In and out of battle the Guards' discipline is an asset to our nation.—I am, etc.,

Moorgate, E.C.2. F. A. Bearn.

Sir,—The question of stamping very rightly raised by Sir Lenthal Cheatle is perhaps not quite so simple as it looks. Most drills produce co-ordinated sound designedly to facilitate synchronous movement, and therefore this is important up to a point; but it must not be denied that stamping can produce some most undesirable results in unsuitable personnel; also the Service boot cannot be entirely divorced from this question, as it is by no means everybody's footwear.

As one who was S.M.O. of a Marine Headquarters for nearly five war years I did raise the question, suggesting that if there was no adequate substitute it would be better to acclimatize recruits with extra P.T. and games while their physique was putting on that initial improvement which practically always occurs after joining, and then a little later putting them on to drill in boots. One undoubtedly gets cases of flat-foot and hallux valgus which develop and get much worse once certain types are put into boots and drilled on the square, even though they have been postmen or milk roundsmen in civil life!

At the same time, without wishing to give this question a psychiatric twist, I must honestly say that, as with so many other physical defects in actual Service practice, the greatest trouble occurs from the unwilling "trading" on their feet; and it is this last feature and many similar ones which largely render conscripting a man over, say, 33 years a dip in a lucky bag of many blanks and very few prizes.—I am, etc.,

Kingsbridge. L. A. Moncrieff,
Surg. Capt., R.N. (ret.).

Terminological Exactitude in Haematology

Sir,—Mr. R. A. Hughes (Dec. 1, p. 782) asks medical etymologists to produce "a term other than 'macrocyte' for the description of cells of large volume." Surely a task of more immediate importance is to clarify the terms in common use. Thus many writers tell us that pernicious anaemia is a macrocytic anaemia, in which the increase in the average size of the red corpuscles is due to abnormal maturation of the megaloblast. Then, again, Mr. Hughes himself appears to think that a macrocyte is a cell of large volume, but, in spite of etymological considerations, it is a universal practice to use the name to designate a corpuscle (not a cell) of large volume. In "red-corpusculology" the termination "blast" is used for nucleated elements.

It is probably impossible at present to reach unanimity about the characters that entitle a cell to be called a megaloblast, but we can at least be sufficiently logical to call its offspring a megalocyte. Then, if we hold that, in certain conditions, a large normoblast may lose its nucleus we shall do well to call the resulting corpuscle a macrocyte. And let us beware of the slipshod habit of using "red cell" as a synonym for "red corpuscle."

It is hoped that the peace will permit of the formation of a body of haematologists to discuss the complicated and unwieldy terminology of their subject.—I am, etc.,

London, W.1. A. Piney.

Shortage of Nurses

Sir,—One point about the shortage of nurses has not been made. The pool of trained nurses is not large enough to bear drainage at one time in all the directions indicated. There may be wastage in the Services, though nurses there hold commissioned rank and are all well diluted by medical orderlies. A more extreme form of wastage in my opinion is the direction and enticement of nurses to industrial nursing. It would be interesting to know the numbers of trained nurses at present occupied, probably below their capacity and skill, in ordnance factories, aircraft and munition works, motor firms, and railway companies. It is surely unreasonable at the present time to have nurses waiting for minor accidents preparatory to sending them to hospital out-patient departments; they might with as much justification be spaced out in "mile-castles" along the roads where most of the serious accidents occur.

And, incidentally, if, as appears likely, nursing is going to remain the sole female "directable" occupation, are new recruits to "serfdom" likely to come forward?—I am, etc.,

Bournemouth. T. R. Aynsley.

Welfare Work a Branch of Medicine

Sir,—I think the difference of view as between Dr. Cicely Williams (Dec. 1, p. 786) and myself is apparent only. I am to blame for not defining "welfare work" before asking the question, "Is welfare work really a branch of medicine?" On Dr. Cicely Williams's definition—"teaching a patient to be healthy"—I subscribe fully to the view that this is a branch of medicine.—I am, etc.,

London, W.1. Horder.

Obituary

A. M. CONNELL, CH.M., F.R.C.S.ED.

We regret to record the death in November of Mr. Arthur M. Connell, consulting surgeon to the Sheffield Royal Infirmary and emeritus professor of surgery in the University of Sheffield.

Born at St. Philip, Barbados, in 1871, he came to England to join University College, London, and after clinical study at University College Hospital took the English Conjoint diplomas in 1895 and the F.R.C.S.Ed. in 1899. He received the Ch.M. degree of Sheffield University twenty years later on his appointment to the chair of surgery. Within a year of qualification he had entered the service of the Sheffield Royal Infirmary and its associated medical school, and in 1899 was elected surgeon. He held the professorship from the end of the war of 1914–18 until 1930. After his retirement from the surgical staff of the Royal Infirmary in 1931 under the age rule, he worked in charge of the physiotherapy department of the orthopaedic clinic and so completed fifty years of service. Connell was highly esteemed as a teacher and loved teaching; his clear-cut museum demonstrations and classes in surgical pathology were famous among students. As a clinician and operator he gave house-surgeons and dressers a daily object-lesson in the principles and practice of surgery.

The outbreak of war in 1914 found him in command of the 3rd Northern General Hospital at Sheffield with the rank of lieut.-colonel, R.A.M.C.; in 1917 he was promoted colonel, A.M.S., and became a consulting surgeon to the Northern Command. He received the Territorial Decoration in 1920, and the King of the Belgians made him an Officer in the Order of Leopold. His devoted work for the Royal Infirmary and the city of Sheffield was commemorated in 1931 by the endowment of a bed in his name after a public meeting held in the town hall, and his colleagues presented the portrait which now hangs in the board room recalling the large part he took in modernizing the surgical practice and equipment of the hospital.

Arthur Connell joined the British Medical Association in 1901. He held office as secretary of the Section of Surgery at the Sheffield Annual Meeting of 1908, and vice-president of that Section at Aberdeen in 1914; he was also secretary of the Navy, Army, and Ambulance Section at the London Meeting of 1910.

R. A. CLAYTON RIGBY, L.R.C.P.&S.ED.

Nottingham has sustained a sad loss through the death of its pioneer radiographer, Dr. Clayton Rigby, which occurred after a brief illness on Sept. 26. For over 25 years he had been associated with the growth and development of the radiological department at the Nottingham General Hospital almost from its origin. He saw and was instrumental in its expansion from one small room till it has become a great specialized department with all its various ramifications—deep *x*-ray therapy, radium, etc. Not only at the General Hospital, but also at the Children's, the Ransom Sanatorium, as well as the Nottingham City Hospital and even the Boston Hospital in Lincolnshire, was his advice sought. He was senior medical officer at the Nottingham Corporation ultra-violet clinic. All this extending field of work eventually told its tale, and the ever-increasing strain of the war years has no doubt been the main factor in robbing Nottingham and the county of one of her most experienced and valued citizens; his passing has left an irreplaceable blank. He was a singularly quiet and dignified man, and these traits combined with his vast experience only served to enhance the authority and experience of his opinion to all who had the privilege of seeking his advice.

Rupert Alan Clayton Rigby was born in Ceylon, his father being chaplain to the tea planters. He was educated at Magdalen School and Westminster, and afterwards went to Edinburgh, where he took the Scottish triple qualification. He joined the B.M.A. in 1911, was a Fellow of the Royal Society of Medicine, a member of the British Institute of Radiology and a former medical officer of the *x*-ray and electro-therapeutic department of the Queen's Hospital, Sidcup. During the 1914–18 war he was captain in the R.A.M.C. and radiologist at Salonika, and became president of the Nottinghamshire Branch of the Salonika Reunion Association.

ARTHUR EDMUNDS, C.B., M.S., F.R.C.S.

Mr. Arthur Edmunds, who retired from surgical practice some years ago to live in Kent, died on Nov. 29 at King's College Hospital, London, where he was for a long time a leading figure. Born on April 17, 1874, son of Joseph Edmunds, he was educated at King's College and Hospital, and in the course of a brilliant student career was awarded the university exhibition in zoology and the university scholarship in physiology at the examinations for the B.Sc.Lond. At King's he won the Sambrooke exhibition, three scholarships, and two prizes. At the intermediate M.B.Lond. he won the exhibition and gold medal in physiology and first-class honours in materia medica, and then, after qualifying in 1900 and acting as house-surgeon, he obtained honours in obstetrics at the Final M.B., and the university scholarship and gold medal at the B.S. in 1901, and passed the M.S. examination in 1903. After demonstratorships in the physiological department at King's, Edmunds served as Sambrooke surgical registrar for four years and senior surgical registrar and tutor from 1910 to 1912, when he was appointed assistant surgeon. He reached the full staff in 1919, and was elected consulting surgeon on his retirement in 1934.

He held the temporary rank of surgeon rear-admiral as consulting surgeon to the Royal Navy during the war of 1914–18, and was created C.B. At the Royal College of Surgeons, whose Fellowship he had obtained in 1901, he was Hunterian Professor in 1926 and 1933. In his early days of practice he served for a time on the visiting staffs of the Paddington Green Children's Hospital and the Royal Northern Hospital. He was elected a Fellow of King's College in 1931.

In 1911 Arthur Edmunds was jointly responsible, with T. P. Legge, for revising and largely rewriting the second edition of Watson Cheyne and Burghard's *Manual of Surgical Treatment* in five volumes; and, besides numerous papers on scientific and surgical subjects, he published in 1908 *Glandular Enlargement and Other Diseases of the Lymphatic System.*

MARGARET BALFOUR, C.B.E., M.D., F.R.C.O.G.

A long life of service on behalf of Indian women is recalled by the death of Dr. Margaret Balfour, which took place at her home in South-East London on Dec. 1. She had spent more than thirty years in India, and even after her retirement from official positions in that country she still interested herself in Indian social conditions and did whatever she could for the Indian mother and her child.

Margaret Ida Balfour was born eighty years ago, the daughter of Robert Balfour, a chartered accountant of Edinburgh. She had her medical training at the School of Medicine for Women, Edinburgh, and qualified in 1891. Then after taking the M.D. of Brussels she went out to India as medical officer in charge of the zenana hospital at Ludhiana in the Punjab. She was one of the most enthusiastic supporters of the great work undertaken by Lady Dufferin's Fund. This work had been inaugurated about seven years previously, during the Earl of Dufferin's viceroyalty. It it said that Queen Victoria herself specially charged the Vicereine to do something to help the women of India in sickness. The aim of the Fund was to provide better medical treatment by the establishment of hospitals and dispensaries and in other ways, especially for the women who were prevented by the restrictions of purdah from being attended by male doctors.

At Ludhiana a medical school for women was founded two years after Margaret Balfour's arrival, but at that time there were only one or two Indian women qualified in medicine, and the vastness of the social need might well have depressed less ardent spirits than Margaret Balfour and Mary Scharlieb and others who determined to bring the resources of Western knowledge and skill to their Indian sisters, especially in childbirth. Women doctors were brought out from Britain, as well as nurses and midwives, and later Indian women were admitted to medical schools and colleges. After three years at Ludhiana Margaret Balfour became medical superintendent of the Dufferin hospital at Nahan, also in the Punjab, where she remained until 1902, and then for eleven years she was medical superintendent of the Dufferin Hospital at Patiala. By the time she had completed her term there modern child welfare was making headway in India, infant welfare centres were multiplying, and ante-natal work was becoming appreciated. For two years after completing her task at Patiala she worked as assistant to the inspector-general of civil hospitals in the Punjab, but in 1916 she returned to the Countess of Dufferin's Fund and served it for eight further years as joint secretary at Delhi and Simla. During that time, to facilitate administration, a separate Women's Medical Service for India was created.

though still under the council of the Fund, and of this service she was chief medical officer from its start until 1924. In that year she ended her official work in India, but not her labours on behalf of Indian women. In 1929 she, with Dr. Ruth Young, published a history of the work of medical women in India—a very lucid record, moderate in its expression, but setting out the plain facts of the social conditions as she had seen them during her long experience. In the following year she published the results of an investigation she had undertaken into maternity conditions among women mill-workers in Bombay. She had specially investigated the diet of pregnant women in that Province, and one interesting observation was that when half the calories of the women's diet were derived from polished rice the proportion of premature births went up to 20%, and when half the calories were derived from wheat there were in her sample no cases of premature birth at all.

On her return to this country she pleaded on many occasions for the employment of more women doctors in India and for a sufficient supply of drugs. She also interested herself in the care of the expectant and nursing mother under industrial conditions in this country. The Council of Action published in 1935—and republished in 1938—a pamphlet by her and Dr. Joan Drury setting out the results of an investigation of motherhood in special areas of the county of Durham and Tyneside. The inquiry was conducted on sociological rather than on medical lines, and special attention was paid to the diet of the expectant mothers. She became in 1929 a Fellow of the Royal College of Obstetricians and Gynaecologists, and from time to tmie she published papers on obstetrics and infant care.

In 1920 Dr. Balfour received the Kaisar-i-Hind medal for conspicuous service in India, and in 1924 she was made a C.B.E. She was a member of the National Council of Women and of the Medical Women's Federation. She joined the British Medical Association as long ago as 1899, and in 1932 she assisted the Association on a committee which it set up to consider the medical aspects of the report of the Indian Round Table Conference. In the three following years she was a member of the I.M.S. Committee of the Association and of the Dominions Subcommittee on India. She retained remarkable vigour of mind and body until within a few days of her death.

Dr. **KENNETH STOCKS BROWN**, who died at Grange-over-Sands, Lancashire, on Nov. 4, after seven years of failing health, studied medicine at the University of Edinburgh and graduated M.B., Ch.B. in 1920. He served as resident house-physician and house-surgeon at Leith Hospital, was then appointed house-physician at the Royal Infirmary, Sunderland, and from 1923 to 1931 held the post of assistant pathologist there. He next became assistant R.M.O. at the Westmorland Sanatorium, Grange-over-Sands, but chronic chest trouble forced him to relinquish that in 1938 and live the life of a comparative invalid. Dr. Kenneth Brown joined the B.M.A. in 1922 and was a member of the Association of Clinical Pathologists.

Dr. **BURGESS MACPHEE**, a retired consultant tuberculosis officer of the Lancashire County Council, died on Nov. 10, aged 68, at Chichester, where he had recently gone to reside after leaving Blackburn. He was born in the Glasgow district in 1877, qualified as M.B., Ch.B. (with distinction) at Glasgow University in 1900, and took the Cambridge D.P.H. in 1912. After graduation he devoted five years to general practice, and then held appointments under the Metropolitan Asylums Board, Surrey County Council, Glasgow Corporation, and at Southampton. He joined the staff of the Lancashire County Council in 1913, and until he left the county service on superannuation in February, 1942, he held the post of consultant tuberculosis officer of a dispensary area (population 330,000) in East Lancashire, with dispensaries at Accrington, Nelson, Stacksteads, and Darwen, and a pulmonary hospital at Withnell, near Chorley. MacPhee played an important part in building up the Lancashire County Scheme for the prevention and treatment of tuberculosis. He was a model consultant physician and a man of sterling character. Held in very great esteem by his medical colleagues, he was much missed when he retired three years ago. He leaves a widow, two sons, and one daughter; a third son, in the R.A.F., was lost over Germany towards the end of the war.

Dr. **EVELYN B. JACQUES**, who died in London on Nov. 21, was the wife of Dr. F. V. Jacques, who was announced as being released from internment in Japanese hands in the *Journal* of Sept. 29. Evelyn Bessie Salter studied medicine at the University of Bristol, graduating M.B., Ch.B. in 1919, and took the D.T.M.&H. two years later, after serving as resident obstetric officer at the Bristol Royal Infirmary. She joined the Malayan Medical Service as lady medical officer at Seremban. Dr. Ann Harling writes: I only knew Evelyn Jacques for the last three years of her life, but I formed a deep admiration and affection for her. Others may be able to tell of her exciting and unusual childhood on board her father's steamship, of scanty schooling except from her mother, and at schools all over the world until she was 15 years old; of her student and postgraduate years at Bristol during and after the first world war, and of twenty years with her husband in the Malayan Medical Service. I learnt only a little of these things, for she was not one to speak of herself. She was a most kind, generous, and loyal colleague, a very good doctor, much loved by many people here in Worcester Park. She bore the years of her husband's internment in Singapore with great fortitude and an irresistible hope that he was alive and would come home again. When he did come home in September of this year she had already suffered from months of the illness from which she died. She had to know both the diagnosis and the prognosis (it was a thing which could not long be hidden from a medical mind) and she lived through this experience with inspiring courage and gaiety of spirit. During the last few weeks she displayed the greatest thoughtfulness for others in spite of very severe pain and enormous doses of morphia. Her life and her death have been an inspiration to all who had the honour to know her. Our deepest sympathies go to her husband, Dr. Frederick Jacques, and her four children, who have all shown the same courage and fortitude.

Mr. **JOHN WILLIAM HEEKES**, for twenty years on the honorary staff of the Royal Hospital, Richmond, Surrey, died at his home in Barnes on Nov. 22, aged 73. He was educated at the City of London School and King's College School, and at Charing Cross Hospital, where, after qualifying in 1906, he became house-surgeon and resident obstetrical officer and clinical assistant in the throat and ear and the women's departments. During the war of 1914–18 he held a commission as captain in the R.A.M.C., serving with the B.E.F. in France and with the Mediterranean Force, mainly in Malta, and afterwards as surgical specialist at the Military Hospital, Belmont. He graduated M.B., B.S.Lond. in 1917, and was for a time surgeon at the Queen Alexandra Military Hospital, Millbank. Returning to practice in the Thames Valley he was appointed surgeon and gynaecologist at the Royal Hospital, Richmond, and visiting surgeon to the Richmond Infirmary. In 1929 he became examiner in gynaecology for the General Nursing Council. He had joined the B.M.A. in 1909, was chairman of the Richmond Division in 1931–2, and represented it at the Annual Meeting at Bournemouth in 1934. Heekes wrote a number of papers on surgical subjects, which were published in these columns between 1907 and 1924, and during the present war he worked as surgeon attached to the Emergency Medical Service.

Industrial medicine has lost one of its most distinguished pioneers with the passing of Dr. W. **DAVID JENKINS**, chief medical officer to the South Metropolitan Gas Company. He was a student of the Middlesex Hospital, and before studying medicine took a B.A. degree with honours in the University of Wales. At the outbreak of the war of 1914–18 he volunteered as a combatant and was commissioned in the Royal Artillery, and saw active service until he was invalided home in December, 1917. He then returned to his medical studies and qualified as M.R.C.S., L.R.C.P. in 1921. Subsequent to this he practised in South Wales and was commissioned as a Justice of the Peace in the County of Glamorgan. Dr. Jenkins was one of the founder members of the Association of Industrial Medical Officers, and gave good service as a member of the executive committee. He joined the South Metropolitan Gas Company in 1932, and with the company's close support introduced a medical service of the highest order. He studied the occupational hazards of the gas industry with an enthusiasm which was most infectious, and became a leading authority on the causation, prevention, and treatment of pitch and tar cancer. His contributions to medical knowledge were made more by the spoken than by the written word. A few weeks before his death he arranged with the collaboration of his company a practical demonstration of the industrial problems in this field for the advisory panel on dermatological problems in industry to the Minister of Labour and National Service. He was a Freeman of the City of London, and was intimately connected with the work of the St. John Ambulance Brigade in London. At the time of his death he was surgeon to the Brigade in the County of London. He was a prominent member of the Savage Club. Dr. Jenkins was a man of outstanding personality, of great courage and charm, and possessed an aptitude for the clear expression of his opinions. With all this, and his specialized knowledge in the field of industrial health, he will be remembered by all who worked with him, whether as a worker, employer, or as a medical colleague, until they too pass on, as a man of great humanity, honesty, and unselfishness, and we his friends for many years will feel the loss of his impartial counsel and courageous presence.—A. J. A. and E. R. A. M.

Medical Notes in Parliament

Sale and Purchase of Practices

Mr. Somerville Hastings on Dec. 6 asked the Minister of Health whether he was prepared to offer any advice to doctors demobilized from the Forces as to the purchase of a practice.

Mr. Bevan replied: The Government have not yet finally decided upon the proposals which they will be submitting to Parliament for a National Health Service. They believe, however, that it will be incompatible with the provision of an efficient service that the future exchange of medical practices and the creation of new practices within that service should be left entirely unregulated and that no effective steps should be taken to secure a proper distribution of doctors to fit the public need. They appreciate that intervention in this field—in whatever form it may take—will probably have the effect of preventing the sale and purchase of the practices of doctors taking part in the new service, and the Government therefore think it right to give warning of this probability at once and in advance of the formulation of their full proposals. At the same time, and in order to allay the natural anxieties of doctors already in practice or now coming into practice from the Forces or elsewhere, the Government wish to make it clear that there will be an appropriate measure of compensation to doctors in respect of loss of capital values directly caused by the new arrangements. It is intended that discussions should be undertaken immediately with the profession's representatives with regard to the steps to be taken to give effect to this decision.

Mr. Hastings asked if Mr. Bevan could suggest what occupation or what branch of the profession medical men returning from the Forces should take if they were not to buy practices. Mr. Bevan said it was hard to frame precise proposals in this matter ahead of legislation. He had informed doctors that it was highly improbable that he would permit the sale and purchase of practices in future, subject to the proposals laid before Parliament. However, arrangements would be made with the medical profession immediately in order to deal with individual difficulties of doctors returning from the Services.

Mr. Willink asked whether the Minister was aware that this vague and menacing statement would cause the greatest possible anxiety and distress among a section of the population to whom the goodwill they had built up was their major asset, and that many of Mr. Bevan's present colleagues in the Government agreed that this was a matter of great complication and not essential to the introduction of a National Health Service. Mr. Willink further asked what Mr. Bevan meant by his allusion to a method of regulating the distribution of doctors.

Mr. Bevan said he had every reason to believe that the announcement just made would be received with great satisfaction by most doctors; that most of the best elements of the profession regarded the sale and purchase of practices as extremely undesirable; and that they would be very glad indeed that he was about to discuss with them the conditions in which this practice was to cease. He added that his answer did not apply to dental surgeons.

Colonel Stoddart-Scott inquired whether the reply meant that doctors who could no longer purchase practices would no longer be able to choose in what part of the country they wished to practise. Did it mean that they would be directed or posted in future? Mr. Bevan asked Colonel Stoddart-Scott to await the full proposals.

Major Lloyd gave notice that he proposed to raise this matter on the adjournment. Mr. Speaker stated that as the matter involved legislation it was bound to be out of order on the adjournment.

Purchase Tax on Doctors' Cars

Major Tufton Beamish on Nov. 29 moved a new clause to the Finance Bill. This proposed that motor cars for use by registered medical practitioners or by veterinary surgeons should be exempted, like ambulances and invalid carriages, from the Purchase Tax. Major Beamish said he had asked the Minister of Health for his support, but had received a letter saying this could not be given and that doctors were not unfairly treated in the matter. The Minister of War Transport and the Chancellor of the Exchequer had said that there were administrative difficulties in the way of the concession. Mr. Dalton had pointed out that the tax was charged at the wholesale stage when the ultimate purchaser was unknown, but Major Beamish argued that it would be easy to refund the tax to doctors who had bought cars subject to Purchase Tax. If doctors did use the cars for pleasure in their scanty leisure hours the House should not begrudge them. Doctors were being demobilized all too slowly. In civil life there was one doctor to 1,300 or 1,400 persons; that proved that a car was indispensable to a doctor. The argument that doctors might resell the car at a considerable profit was invalid, because there were stringent conditions of resale. County medical committees could ensure that only practising doctors were afforded this relief.

Mr. Glenvil Hall said the amendment as drafted was unworkable. It meant that a doctor who wished to go anywhere, save on a professional visit, must keep two cars or walk. The tax was imposed at the wholesale stage, when it was impossible to know who would buy or use the car. Doctors deserved all the sympathy and help the House could give them, but it could not be given this way.

The proposed new clause was negatived.

Physiotherapists in N.H.S. Consultations

On Nov. 29 Sir Ian Fraser asked the Minister of Health if he would give the profession of physiotherapy the same opportunity of consultation as he had offered to the medical profession before he introduced his proposed National Health Service Bill. Mr. Bevan: I shall be glad to consider any views which the physiotherapists care to put before me.

Empire and United Kingdom Casualties

Total casualties suffered by the armed Forces of the British Commonwealth and Empire from Sept. 3, 1939, to Aug. 14, 1945, were given by Mr. Attlee as 1,246,025, including 353,652 killed and 475,070 wounded. Casualties for the United Kingdom were 755,257, including 244,723 killed and 53,039 missing, 77,090 wounded, and 180,405 prisoners of war. Casualties to merchant seamen included 30,189 deaths.

Doctors in East Africa Command

Colonel Price-White on Dec. 4 asked the Secretary of State for War if he was aware that under present military establishments and commitments in East Africa Command at least one-half of the staffs of medical services in that command were surplus to requirements. In view of the shortage of civilian doctors and staffs in Britain he asked the Minister to arrange for the early repatriation and release of those now so redundant. Mr. Lawson denied that the position was as stated. He said that in addition to the British troops there was a very large number of Colonial troops for whom medical attention had to be provided by the R.A.M.C. Certain reductions were recently ordered, and all medical officers in Group 24 or earlier were being returned for release in December, but it would be quite impossible to reduce by anything approaching 50%.

Milk for the Tuberculous.—Tuberculous patients are allowed a priority supply of fourteen pints of milk a week in addition to normal rations and allowances. Sir Ben Smith is advised that this provision is adequate for their needs. It is fixed on the advice of medical experts. Mr. Bevan states that tuberculous patients in civil hospitals are entitled to special supplements of ordinary civilian rations and to two pints of milk a day in addition. He is advised that this dietary compares favourably with that laid down for military hospitals.

Stakehill Detention Barracks.—Mr. Driberg on Nov. 27 referred to Stakehill Detention Barracks and to a case there last year of an apparently fit man who went into the barracks and was dead within three days. No inquest was held. The relatives saw the body with the forehead bruised and a bruise on the neck. Major Wyatt said death took place after this man had been made to run a mile in seven minutes wearing full kit. On entering the camp he had been passed by the camp doctor as fit to take such exercise. He should not have been passed as fit if he was going to collapse and die of heart failure after running a mile. Dr Morgan asked the War Office to see that proper arrangements were made in detention camps from a psychiatric point of view. Few psychiatrists attended the camps. Mr. Lawson said it was necessary that the inquiry which had been ordered should be private. He did not exclude a public inquiry later into the general question of Stakehill.

Immunization of Children.—Mr. Bevan states that returns received from all but a few local authorities indicate that during the six months to June 30, 1945, 201,465 children under 5, and 65,469 between 5 and 15, were immunized under local authority arrangements in England and Wales: that of 6,168 children notified as suffering from diphtheria 1,959 were immunized and 4,209 unimmunized; and that of 289 children who died from diphtheria 24 were immunized and 265 unimmunized. He adds that a true statistical assessment of the results of immunization in the current year must await the Registrar-General's conclusions, which are normally published in the Ministry's annual report.

Medical Students' Fees.—Mr. Bevan said on Nov. 29 that he was not empowered to make grants to relieve students taking recognized courses for a degree in medicine of the greater part of their fees. Assistance was available to medical students from various sources, including scholarships awarded by the Ministry of Education, by local education authorities, and by medical schools.

Public Assistance Mental Patients.—Mr. BEVAN stated that on Jan. 1, 1945, there were under the Lunacy and Mental Treatment Acts 10,550 persons in public assistance institutions or wards of municipal general hospitals approved for the purpose by local authorities under Section 19 of the Mental Treatment Act. On the same date there were 9,852 mental defectives in public assistance institutions which had been approved for the purpose under Section 37 of the Mental Deficiency Act, 1913. A considerable proportion of these patients required only to be looked after. Those needing treatment received it from the medical officers of the institution.

Notes in Brief

Mr. Attlee said on Dec 3 that he hoped to make another statement soon on the control of atomic energy.

Sir Stafford Cripps states that in 1935, the latest year for which figures are available, 20% of the British production of drugs, medicines, and medicinal preparations was exported.

EPIDEMIOLOGICAL NOTES

Discussion of Table

In *England and Wales* infectious diseases were more prevalent, the rises over last week's totals being: scarlet fever 237, acute pneumonia 159, measles 50, dysentery 43, whooping-cough 29.

Scarlet fever increased mainly in the Midlands, and to a less degree in London and the south-east.

Diphtheria notifications in Lancashire showed an increase of 19 cases over last week's total, but fell by 15 in Yorks West Riding and by 11 in London. The chief centres of infection are in Liverpool C.B. 56, and Birmingham C.B. 31, these two cities accounting for over one-eighth of the total notifications. Pneumonia was prevalent in the north.

There were 40 more cases of measles in Suffolk than last week.

No fresh outbreak of dysentery was recorded during the week. The largest returns were London 32, Lancashire 28, Warwickshire 21, Glamorganshire 20, Middlesex 19, Surrey 14, Gloucestershire 12.

In *Scotland* diphtheria, with 206 notifications, reached the highest level of recent months. The largest returns were Glasgow 66 and Edinburgh 28. The total notifications for acute primary pneumonia and for scarlet fever were respectively 33 and 15 higher than last week.

In *Eire* the outbreak of measles in Dublin C.B. continued, notifications mounting from 113 to 146. The incidence of diphtheria for the whole country fell by 7 and of whooping-cough by 6, but that for scarlet fever rose by 15. In Dublin the figure for diarrhoea and enteritis rose by 12 to a total of 45.

In *Northern Ireland* scarlet fever, with 53 notifications, is more prevalent than during the past six months.

Infantile Paralysis in Queensland

An outbreak of infantile paralysis centred in Brisbane has spread throughout Queensland; 191 cases with 5 deaths have been reported; 60% of the cases occurred in Brisbane.

Quarterly Returns for Scotland

The birth rate during the September quarter was equivalent to 16.4 per 1,000, which is 1.1 below the average of the five preceding third quarters and the lowest rate ever recorded in a third quarter. Infant mortality was 46 per 1,000 registered live births—14 below the five-years average and much the lowest rate ever recorded in Scotland. The previous lowest infant mortality for any quarter was 55, this level being reached on three occasions. The maternal mortality, 2.2 per 1,000 live births, was the lowest ever recorded for any quarter. The general death rate, 10.9 per 1,000, was 0.8 below the average of the five preceding third quarters and was the lowest recorded for any quarter since 1939. Deaths from the principal epidemic diseases numbered 67, and included 20 from diphtheria, 15 from measles, 13 from cerebrospinal fever, and 10 from whooping-cough. Tuberculosis caused 850 deaths, the death rate from all forms being 70 per 100,000 54 from respiratory tuberculosis). The former rate is 8 below that for the third quarter of 1944, and the latter is 5 below; the death rate for respiratory tuberculosis was the same as while that for all forms was 3 below, the five-years average. The marriage rate was 10.5 per 1,000; only on two occasions have higher rates been recorded for any quarter—those for the third quarters of 1939 and 1940, when they were 12.4 and 12.3 respectively.

Week Ending December 1

The notifications of infectious diseases in England and Wales during the week included: scarlet fever 1,879, whooping-cough 1,384, diphtheria 676, measles 501, acute pneumonia 746, cerebrospinal fever 45, dysentery 231, paratyphoid 6, typhoid 12, poliomyelitis 20.

No. 47

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended Nov. 24.

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for: (a) England and Wales (London included). (b) London (administrative county). (c) Scotland. (d) Eire. (e) Northern Ireland.

Figures of Births and Deaths, and of Deaths recorded under each infectious disease, are for: (a) The 126 great towns in England and Wales (including London). (b) London (administrative county). (c) The 16 principal towns in Scotland. (d) The 13 principal towns in Eire. (e) The 10 principal towns in Northern Ireland.

A dash — denotes no cases; a blank space denotes disease not notifiable or no return available.

Disease	1945					1944 (Corresponding Week)

Rate per 1,000 total births (including stillborn)			30					39		

* Measles and whooping-cough are not notifiable in Scotland, and the returns are therefore an approximation only.

† Includes primary form for England and Wales, London (administrative county), and Northern Ireland.

‡ Includes puerperal fever for England and Wales and Eire.

§ Owing to movements of population, birth and death rates for Northern Ireland are still not available.

Medical News

The fourth annual general meeting of the Anglo-Soviet Medical Council will be held on Tuesday, Dec. 18, at 4.30 p.m., at the Royal Society of Medicine, 1, Wimpole Street, W. Prof. Arnold Sorsby, F.R.C.S., will speak on Soviet medicine.

A meeting of the Eugenics Society will be held at the rooms of the Royal Society (Burlington House, Piccadilly, W.) on Tuesday, Dec. 18, at 5.30 p.m., when Dr. D. V. Glass will give an address on "Aspects of the Development of Population Policy." All interested are invited to attend.

A meeting of the Colour Group of the Physical Society will be held at 3.30 p.m. on Wednesday, Dec. 19, in the small Physics Lecture Theatre, Imperial College, Imperial Institute Road, S.W., when a lecture on "Colour Discrimination, the Visibility Curve, and the Trichromatic Theory" by W. S. Stiles, D.Sc., will be followed by an informal discussion.

A meeting of the British Institute of Radiology will be held at 32, Welbeck Street, W., on Thursday, Dec. 20, at 8 p.m., when a paper by Mr. M. H. Jupe and Mr. L. A. Kemp on "The Physicist in the Radio-diagnosis Department" will be read. On Friday, Dec. 21, at 5 p.m., there will be a meeting of medical members at the same place. The Diagnosis Section of the Faculty of Radiologists will meet at the Royal College of Surgeons of England on Friday, Dec. 21, at 2.30 p.m., when there will be a discussion on "The Radiology of Non-malignant Intracranial Lesions."

The London County Council announces the retirement of Sir Thomas Carey Evans, F.R.C.S., medical superintendent of Hammersmith Hospital. His retirement is on medical grounds. The Council states that Sir Thomas Carey Evans, who entered its service in 1931, has shown himself to be a most capable organizer and medical administrator. "His professional ability, tact, and charm of manner have impressed all those with whom he has worked and have greatly contributed to the establishment of the amicable relations which exist between Hammersmith Hospital and the British Postgraduate Medical School."

Lieut.-Col. the Right Hon. Walter Elliot, F.R.S., F.R.C.P., of Bonchester Bridge, Hawick, has been appointed a Deputy Lieutenant of the County of Roxburgh. Dr. E. W. Jones, of Llety'r Eos Llanfairtalhaearn, and Seibiant, Pontllyfni, has been nominated Sheriff for the County of Caernarvonshire.

The appointment of Dr. Stuart I. A. Laidlaw as Medical Officer of Health for Glasgow in succession to Sir Alexander Macgregor, who retires in April, has been confirmed by the City of Glasgow Corporation.

Universities and Colleges

UNIVERSITY OF CAMBRIDGE

Postgraduate Courses for Ex-Service M.O.s

It is proposed to hold 14-day refresher courses for medical officers released from the Forces as follows: Pulmonary tuberculosis, its differential diagnosis and treatment, at Addenbrooke's Hospital, Cambridge, and at Papworth, beginning on Jan. 14, 1946; general 14-day course at Ipswich and Colchester beginning on Feb. 11, 1946; and a 14-day course on social and industrial medicine at Luton beginning on May 6, 1946. Should vacancies occur these courses will be available for general practitioners. Further particulars can be obtained on application to Dr. Douglas Firth, Trinity Hall, Cambridge.

UNIVERSITY OF LONDON

Alan Moncrieff, M.D., F.R.C.P., has been appointed to the Nuffield Chair of Child Health tenable at the Institute of Child Health as from Jan. 1, 1946. He is a member of the staff of Middlesex Hospital and the Hospital for Sick Children and is also paediatrician to Queen Charlotte's Maternity Hospital and to the British Postgraduate Medical School. During the war he has served as wholetime physician to the Emergency Medical Service.

UNIVERSITY OF DUBLIN

SCHOOL OF PHYSIC, TRINITY COLLEGE

The following medical degrees were conferred on Dec. 5:

M.D.—P. Delap.
M.CH.—W. Houston.
M.B., B.CH., B.A.O.—P. G. S. Beckett, J. A. D. Bradfield, K. Campbell, D. J. Crowley, W. G. Fegan, A. J. E. FitzGerald, Maire C. FitzPatrick, Joan M. Fox, T. H. F. Gillespie, H. T. C. Hitchcock, P. G. Kennedy, Elizabeth M. Kyle, Elinor W. McCloy, K. A. McFadden, C. W. E. Murphy, G. M. O'Donnell, A. J. H. Reford, Mary A. Wright.

Letters, Notes, and Answers

All communications with regard to editorial business should be addressed to THE EDITOR, BRITISH MEDICAL JOURNAL, B.M.A. HOUSE, TAVISTOCK SQUARE, LONDON, W.C.1. TELEPHONE: EUSTON 2111. TELEGRAMS: *Aitiology Westcent, London.* ORIGINAL ARTICLES AND LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated.

Authors desiring REPRINTS should communicate with the Publishing Manager, B.M.A. House, Tavistock Square, W.C.1, on receipt of proofs. Authors over-seas should indicate on MSS. if reprints are required, as proofs are not sent abroad.

ADVERTISEMENTS should be addressed to the Advertisement Manager, B.M.A. House, Tavistock Square, London, W.C.1 (hours 9 a.m. to 5 p.m.). TELEPHONE: EUSTON 2111. TELEGRAMS: *Articulate Westcent, London.*

MEMBERS' SUBSCRIPTIONS should be sent to the SECRETARY of the Association. TELEPHONE: EUSTON 2111. TELEGRAMS: *Medisecra Westcent, London.*

B.M.A. SCOTTISH OFFICE: 7, Drumsheugh Gardens, Edinburgh.

ANY QUESTIONS?

Road Accidents while "Under the Influence"

Q.—*In charges of being "under the influence of alcohol while driving a car" the defence is often put up that the defendant's condition was due to shock or concussion. Can you help in the differential diagnosis?*

A.—Shock and concussion closely simulate the manifestations of alcoholic intoxication. The issue is liable to be complicated by the defendant having been given an alcoholic stimulant after the accident or by the ingestion of a small quantity of alcohol beforehand, which in itself would not warrant the charge of being "under the influence." The chemical examination of the blood or of the urine for alcohol is of definite value in these cases because the approximate amount of alcohol in the body, and therefore the amount ingested, can readily be determined. For the full value of such a procedure the reader is referred to the *Practitioner*, April, 1945, p. 205.

Salivation

Q.—*A man aged 50, subject to asthma, suffers from troublesome salivation. When he is trying to sleep saliva often gets into his larynx, causing fits of coughing; when asleep saliva occasionally trickles from his lips. He also complains of intestinal flatulence. What is the treatment?*

A.—The causes of salivation are many, though asthma does not appear to be numbered among them. The possibility should nevertheless be borne in mind that a drug used for the treatment of the asthma, such as iodide or arsenic, is irritating the salivary glands. Salivation is usually the result of some local or distal source of irritation. Water-brash is a well-recognized symptom of peptic ulcer, and this would be one's first thought in a case of this kind. However, quite minor digestive upsets will provoke attacks of salivation, which can then be regarded as part of the syndrome of nausea. Patients may salivate after aspirin or after taking rich food and drink. It might therefore be worth while to investigate the digestive symptoms more closely, and if no gross lesion is found an effort should be made to relieve the flatulence by avoidance of potatoes and gassy vegetables. Other common causes are irritation from teeth or dentures and disease of the central nervous system. It is stated that salivation may occur as a functional form of mouth neurosis, whatever that may mean, and there is no doubt that in certain cases the cause remains obscure. If no cause can be found, belladonna or atropine should be prescribed.

Discharge Swabs in Diphtheria

Q.—*With regard to discharge swabs of diphtheria cases* (JOURNAL, *Nov. 24, p. 753*)*, would one be justified in abolishing these altogether provided the child was clinically well and had a normal nasopharynx?*

A.—No, this is not sound practice either administratively or clinically. It is quite true that a child with a normal nasopharynx is unlikely to be either a heavy or a persistent diphtheria carrier. Still, normality in the nasopharynx is an unstable condition, and a child who contracted a respiratory infection soon after discharge from hospital could be converted thereby from a light diphtheria carrier to a potentially dangerous source of infection with a heavily infected droplet spray.

Control of Neurosyphilis

Q.—*When the clinical advancement of neurosyphilis has been checked, after full courses of treatment three years ago, do strongly positive Wassermann and Kahn tests indicate that antisyphilitic treatment should be tried again?*

A.—If the Wassermann and Kahn were *serum* tests the answer is, No. As to whether further treatment is necessary, much depends on four factors: (1) the present condition of the cerebrospinal fluid; (2) the nature of the central nervous system involvement—early or late, meningo-vascular or parenchymatous; (3) age of the infection; and (4) the total amount and nature of the treatment given ("full courses" is a somewhat indefinite expression). Lumbar puncture should be carried out; if the fluid is normal it may be sufficient to keep the patient under observation for another two years, testing the blood serum every 3 to 6 months and the cerebrospinal fluid yearly. A fluid which shows any abnormality is an indication for further treatment no matter what the clinical condition. Serial *quantitative* serum tests should be helpful by indicating whether the infection is advancing or receding.

Calcium in Tuberculosis

Q.—*Which is the best calcium preparation to use in the treatment of tuberculosis?*

A.—There is no definite evidence that patients with tuberculosis suffer from deficiency of calcium or that they benefit from its administration. It is, however, a useful placebo and is entirely harmless. Calcium may be given in the form of calcium gluconate (10 gr. in 10 c.cm. of water by intravenous injection, or 30 gr. by mouth), and the addition of vitamin D aids absorption.

Paroxysmal Auricular Fibrillation

Q.—*The blood pressure of a patient aged 62 has varied from 146/95 to 190/110 for some fifteen years. Five years ago he had a transient hemiplegia, which cleared up within 24 hours and has not recurred. For the last three years he has had increasingly frequent attacks of palpitation with dyspnoea, usually brought on by exercise, and lasting from a few hours to a couple of days. The attacks are incapacitating, and subside without treatment other than rest. An electrocardiogram taken during an attack showed typical auricular fibrillation with auricular rate 600 and ventricular 160. After the attacks a mitral systolic murmur can be heard, but between bouts the heart sounds are normal. Almost all attacks are preceded, sometimes two hours before, by frequency of micturition, which continues during the attack and ceases when it subsides. Is there any explanation of the syndrome?*

A.—This is evidently a case of paroxysmal auricular fibrillation of the "senile" type. The occurrence of such attacks, if they are sufficiently frequent to make it worth while, can sometimes be reduced by quinidine sulphate, 6 to 9 gr. daily. The frequency of micturition might serve as a warning to indicate the use of quinidine. What its association with an attack may be is quite obscure. Perhaps there is a nervous cause for both. Any attack lasting more than an hour or so, if the heart rate reaches as high as 160, with the possibility of its lasting some days, is worth treating with quinidine or digitalis—preferably digoxin intravenously.

Synthalin in Diabetes

Q.—*Some of my diabetic patients object to frequent injections of insulin. Can synthalin tablets be recommended to these patients? Are they as efficacious as insulin? Have they any injurious effects on the liver?*

A.—Synthalin was tried in the treatment of diabetes mellitus seventeen years ago (*Proc. roy. Soc. Med.*, 1928, **21**, 527, and *Quart. J. Med.*, 1928, **21**, 509). It lowers the blood sugar of many diabetic patients, and can replace from 10 to 30 units of insulin, but has no effect at all on others. Unfortunately synthalin may cause toxic symptoms, such as nausea, vomiting, and even jaundice, which may be fatal. To reduce this risk it was given in courses of three days with one day's rest, and so on. In spite of these precautions toxic symptoms developed, and its use hardly seems justified nowadays. The discovery of the slow-acting insulins—protamine-zinc and globin insulins—has made it possible to control the diabetic condition reasonably well with one dose a day. This should not be an intolerable burden for patients once they realize the benefit they receive.

Blood Tests for Non-paternity

Q.—*What is the present-day opinion on tests for paternity? A male patient of nine has been accused, and is willing to undergo any tests to prove his innocence.*

A.—Blood tests for non-paternity, as it is more correct to call them, are regarded by most courts nowadays as reliable if performed by a competent person. They consist in the determination of the inheritable blood characters of the mother, the child, and the suspected father. Several sets of inheritable characters are now recognized. Broadly speaking, if the child's blood contains a group character which does not appear in the blood of the mother he must have inherited it from his father, and so if the suspect's blood does not contain it either, the suspect is not the father. The suspect's chances of being exonerated by blood-group tests vary according to the rarity of the child's aggregate of characters, but the average is a good enough chance to be worth trying. If the mother is willing to co-operate, the parties should write to the Director of the Department of Chemical Pathology, St. Mary's Hospital, London, W.2.

Willow Contact Dermatitis?

Q.—*Has the willow tree (Salix alba coerulea) any allergic property? A man who has been measuring a large number of them—almost embracing them and perhaps touching them with his face—has developed an oedematous condition of the face, neck, and back of the right hand, which has become slightly scaly with some "weeping" at the back of the neck. He has no constitutional symptoms.*

A.—A large number of plants and woods are reputed to cause contact dermatitis, but it would seem that the willow has not been specially mentioned in this connexion. The story, while suspicious, is by no means convincing. A patch test with wet sawdust should give a reaction if specific sensitivity exists. Patch-testing is valueless and even misleading unless carried out in the approved manner and with suitable controls.

Immediate Reaction to Revaccination

Q.—*Some authorities maintain that the immediate reaction to revaccination is an allergic phenomenon, because it can be obtained with killed virus, while others consider that it denotes a high degree of resistance. Has this point been settled by estimating the antibody content of the serum of those persons giving the immediate reaction to revaccination?*

A.—There is no necessary antithesis between these two ideas. The immediate reaction is commonly regarded as allergic for the reason given, but some degree of immunity is necessary for its production. Clinical evidence suggests, however, that the degree necessary is partial rather than "high." We know of no observation on the antibody content of the blood in such subjects.

Repeated Neonatal Deaths

Q.—*Can you explain a case of repeated neonatal deaths? The wife of an Indian official has had eight children. Two of them survived and the other six all died within a few hours of birth. They were all a little short of full term, but apparently perfectly healthy. Both parents have had Wassermann and Kahn tests done repeatedly. There were no necropsies, but I cannot imagine any congenital defect incompatible with life which would be repeated in six children There is no history of malaria and the woman herself is healthy.*

A.—The history of repeated neonatal deaths without evidence of syphilis or other obvious disease suggests that iso-immunization in pregnancy may be the cause of the disasters, Rh incompatibility being the likeliest basis, with the father Rh-positive and the mother Rh-negative.

When the foetuses reach almost full term but die within a few hours of birth, evidence of haemolytic disease may be detectable only by post-mortem examination; commencing jaundice and petechial haemorrhages may easily escape recognition in dark-skinned infants. The writer does not state whether the two surviving children are the first and second infants, as is usual in haemolytic disease, but if so the six successive disasters suggest that the father is homozygous Rh-positive—RhRh—and if that is so all subsequent children will be affected since all will be Rh-positive. If, however, the two surviving children have been interspersed with those dying soon after birth, either the cause is not iso-immunization or the father must be heterozygous Rh-positive—Rhrh—with the probability that at least the younger child is Rh-negative. In this case there would be a 50% chance of each future child escaping haemolytic disease through being Rh-negative. It is unlikely that the case could be satisfactorily investigated in Kenya, but perhaps the blood of the parents could be examined in South Africa. It should be possible, however, to send specimens of whole blood by air to this country and the bloods could be typed at one of the Regional Blood Transfusion Centres. If the questioner were sufficiently practised in blood grouping he might be able to detect Rh sensitization in the mother by the open slide test of Diamond and Abelsom (*J. Lab. clin. Med.*, 1945, **30**, 668), testing the wife's blood against the husband's if the ABO groups permit.

INCOME TAX

Military Pay for Period of Return Voyage

"MAJOR" served over-seas from March 11, 1937, to June 26, 1943, being paid by the Indian Government and suffering Indian income tax. The period March 23, 1943, to June 26, 1943, was spent in travelling back to this country, and for that period pay was due at British rates by the British Government. Is British tax due on the pay for that period?

⁂ The pay for the three months in question is apparently within the scope of Schedule E of the British income-tax code, which applies to "every public office or employment of profit and in respect of every annuity, pension, or stipend payable by the Crown or out of the public revenues of the United Kingdom." The fact that "Major" was not liable on the pay issued from Indian sources for an earlier period of foreign service does not affect his subsequent liability.

LETTERS, NOTES, ETC.

Problem for Bibliophils

Lieut.-Gen. Sir W. P. MACARTHUR writes: I shall be grateful if any reader can help me by identifying a book from the following scanty details. It deals in part with plague in the past, and the illustrations include one of an ancient Roman design which shows a rat identified in the text as *Rattus norvegicus*—convincingly so to my recollection. The picture might possibly be a reproduction of the rat shown on the first-century Roman altar discovered in Rheims, but my hazy recollection is that it appears on an independent medallion. The point does not affect the value of the clue. I have tried in vain to find the book in a number of libraries, which is not surprising, as I can recall neither the title nor the author's name.

Some Suggestions and Suggestive Questions

Dr. E. W. MORGAN (London, W.11) in the course of a letter suggests that in order to avoid being confined to the restricting and restricted service of the State, which has been threatened so long, the British medical profession should join, or allow itself to be joined with, the other medical professions of the world. He goes on to show how mankind could benefit from the co-operation of medical workers among all peoples. It might, he says, even be a check against future war. Should doctors, for health or other good reasons, leave their native lands they could practise wherever they went; lack of knowledge of languages would not obstruct successful surgical manipulations, since there are enough interpreters to deal with medical history-taking. Continuing with some other suggestions, he says that every part of the British medical profession should examine itself to see where improvements are needed. Are the most suitable often enough appointed to teaching hospital staffs? Should the motives of prospective students be inquired into? Is it good that every practising doctor should be moved mostly by compassion for the sick? If so, let this be recognized, and if there are any who are not thus moved let them be guided to the laboratories, the libraries, the museums, the post-mortem rooms, etc. Is it also good for at least one or two general practitioners to serve on a hospital staff? Should hospital appointments be permanent, or should there be opportunity for change of staff if efficiency is not maintained? Is teaching of the most valuable facts, for practical purposes, sacrificed for the sake of knowledge of the whole subject, however superficial? Should the medical student's course be less intensive and exhaustive? Can anything be done to see that students find the most suitable work? He considers that some minds are built for psychological work; some arms and hands are made for orthopaedic work; some fingers are delicate enough for gynaecology; some personalities make excellent children's specialists; some all-round men make good family doctors; etc.

Car Without Foot Pedals?

Dr. C. T. NORRIS (Calne, Wilts) writes: The vehicle Dr. J. Rammell (Sept. 29, p. 450) requires for his patient was seen by me in or about 1930 in a garage I had occasion to patronize in Battersea. Soon after I found this place I was attracted by the unusual appearance of an Austin 7 of the old "bath-tub" type, now obsolete, which appeared to have a stirrup fixed upside down on either side of the steering column below the steering wheel. Inquiry from the garage staff elicited that this car was the property of a man without legs, who, as I myself saw later, appeared to be in quite humble circumstances, and I could well believe that possession of this car made all the difference to his life. The car had been adapted to his needs by the controls from each foot pedal being led from the slots in the floor, after removal of the pedal, up the side of the steering column casing to stirrup-shaped grips, where the fingers of each hand could grasp them while the wheel was still held by the thumbs and palms: thus the stirrup-shaped grip operated the clutch or the foot-brake. If I remember rightly, in order to avoid undue downward pressure on the steering wheel, and to enable one control to be operated firmly while the other hand steered, the movable grip was placed below, and fitting into, a fixed stirrup-shaped fitting; each fitting, therefore, looked like a stirrup with a bar across the opening. In order to enable the gear lever to be used with the clutch out I believe the controls were crossed, the right hand thus operating the clutch and the left the foot-brake. The throttle was operated by a separate lever, such as at that time was often seen on cars for adjustment of the mixture. I seem to remember that the Austin 7 had two such little levers on the wheel—one to adjust the spark and the other the throttle opening—so no special fitting was necessary for that work. But in a similar adaptation of a car to-day no doubt a lever of this kind would be necessary, and could be led up the steering column to below the wheel, or put, like a motor-cycle control, on a cable on one of the fixed stirrup grips. I have gone into the description of this car in some detail as it exactly answered the requirements of Dr. Rammell's patient; and I would suggest his advising a similar adaptation of a suitable vehicle, which any interested garage should be able to carry out. The requirements would appear to be: (1) The car itself must be "light" with light springing on the clutch and foot-brake, otherwise the much smaller force than usual available for operation of these controls will not act, with disastrous results sooner or later. (2) The actual fittings must be adjusted accurately to the hands of the individual who is to drive the car. My inquiries in 1930 elicited that there was then no police or other objection to the car I saw; and I think even in these days of driving tests no reasonable examiner would object to such controls once their use had been learned. I consider the present Austin 8 or any similar car could be equally well adapted in the manner I have tried to describe.

Undervalued Emoluments

"BEARING UP" writes: The position of the hospital M.O. who can, and does, live out must often be uncomfortable if not positively desperate. Before I married I enjoyed (if such a word can be used in this connexion) the "residential emoluments" (hateful phrase!) of my hospital. When I married there was no bar to my living out provided I kept a tame telephone at my own expense, so I blithely set up house and received £150 per annum added to my salary "in lieu of emoluments." I was only mildly dashed to find that this wilted to £75 under the searing hand of the Inland Revenue, but worse was to come. I found that to provide for myself the shelter, food, fuel, light, laundry, and telephone necessary for continued existence cost me £270 per annum. Obviously very heavy inroads had to be made into my salary, otherwise I could have paid the butcher and baker and candlestick-maker only 5s. in the pound. This illustrates the total inadequacy of the living-out allowance under present conditions, and the vicious system of taxing it at full rates. Hospitals which cannot offer adequate married accommodation should certainly be pressed to raise their living-out allowances to a more reasonable figure, but a more urgent demand is that taxation on allowances should be mitigated or abolished. While the present full tax is in force no recipient of a living-out allowance is being justly treated. To live out has non-material advantages, not to be assessed at cash valuation, which offset the debit balance, but I think it unfair that one should have to pay for them so dearly.

Pruritus and Glycosuria

"M.D." writes: Your answers to "Any Questions?" are always most interesting. In the *Journal* of Oct. 20 (p. 556) there is a question on pruritus and glycosuria, on which a note of personal experience may be of use. With most of the answer I agree, but not with the last suggestion to seek another cause. Some years ago I had renal glycosuria, and cut down starches and sugars for a year with good result but loss of weight. I did not, however, resort to insulin. I have had no sugar appreciable for several years now, but can renew my pruritus in a similar region any day by indulging a little in boiled sweets or "tray" chocolates. Ordinary starches—e.g., bread—do not bring it on. Surely it would be worth the lady's while cutting out sweets even if there is a craving. If she does this there may be no need to use insulin or restrict carbohydrates unduly.

Salivary Gland Tumour of Upper Lip

Mr. J. F. CURR, F.R.C.S.Ed., writes: In the *Journal* of Nov. 3 (p. 605) I published a short report on a salivary gland tumour of the upper lip, the condition being fairly uncommon according to previous records. Less than a fortnight later, and on successive days, I saw two more cases, in men aged 31 and 34, the tumours being situated near the lateral end of the lip. Using a local analgesic, each tumour shelled out easily through an incision in the mucous membrane of the lip. The typical appearances of simple, mixed parotid tumour were found on histological examination, for which I wish to thank Dr. R. F. Ogilvie and Dr. W. Forbes.

Wellcome Medical Diary, 1946

The regulations which govern the distribution of printed matter having been relaxed, Burroughs Wellcome and Co. can now issue the very limited edition of the 1946 Medical Diary free of charge. Those who have already sent remittances of 2s. may have them refunded on request. In the absence of such a request, any sum already received will be sent to the Royal Medical Benevolent Fund early in 1946, together with any further moneys received. The diary is being dispatched to all doctors who have asked for a copy. The publishers regret that few, if any, additional requests can be entertained.

Corrections

In Sir Arthur MacNalty's Vicary Lecture on "The Renaissance and its Influence on English Medicine, Surgery, and Public Health" (Dec. 1) "Sir John Elyot" should read "Sir Thomas Elyot," on pp. 757-8.

Dr. J. N. Davidson wishes to correct an error in our issue of Dec. 8 (p. 815). Under "Modern Methods" the third sentence should have read: "Heavy nitrogen (N^{15}), heavy sulphur (S^{34}), deuterium (D), and heavy carbon (C^{13}) had been used in this way."

B.L.A. MEDICINE

BY

ERNEST BULMER, C.B.E., M.D., F.R.C.P.

Lately Brigadier, Consulting Physician, 21 Army Group; Honorary Physician, Birmingham United Hospitals.

FOREWORD BY
Field-Marshal SIR BERNARD MONTGOMERY

"I should like to take this opportunity to pay a tribute to the great work done by our doctors during the campaign in North-Western Europe. It was often unspectacular work, as may be judged from the constantly recurring reports, 'Sickness rates remain low.' But as the result of the immense pains taken our great armies in B.L.A. were far healthier than the armies of the last war; this was achieved in spite of the fact that active large-scale operations continued at a high pitch throughout the campaign, and did not stop during the autumn and winter, when we experienced the worst possible weather conditions.

"The doctors of the B.L.A. can be justly proud of the results which they achieved; these results produced a force ready at all times to meet the great calls made on its endurance and physical fitness. Our doctors have in fact played no small part in the achievement of final victory in Europe."

B.L.A. surgery has been admirably dealt with by Porritt, Debenham, and Ross (1945), and reference should be made to their paper for the operational side; physicians were busiest during static periods, and in battle their work in forward areas was chiefly with chest injuries. Modern warfare in a temperate country has proved a healthy thing, and, unlike the Middle East, North African, and Far Eastern campaigns, medicine has been content to take a second place to surgery. Nevertheless the problems presented to the physician during the several phases of the campaign were varied and urgent, and in the German phase the unexpected responsibility of dealing with mass starvation strained both resources and ingenuity.

I propose to survey the field broadly, and to deal only with the twelve months I was in the theatre—July, 1944, to July, 1945. The observations of the consulting physician to a force of this size must be superficial, as they must equally be extensive; it is anticipated that papers will be published by those who had the opportunity of day-to-day studies, and it is not possible for me here to acknowledge the source of all my remarks.

The Medical "Set-up"

There were complete medical departments in the large base hospitals, with physicians, dermatologists, psychiatrists, venereologists, and neurologists. The field force had experienced physicians in casualty clearing stations and 200-bed hospitals, but they lacked full ancillary services; during battles they co-operated with the surgeons, largely in the treatment of chest wounds, while between battles they were very busy treating the sick. Light sick and skin cases were held in minor medical units with supervision from the nearest physician or dermatologist. The handling of venereal and psychiatric cases was separately organized under the respective Advisers—Lieut.-Col. D. J. Campbell and Lieut.-Col. D. J. Watterson; it will not be discussed here. The whole medical service was co-ordinated by the D.M.S. with the advice of his consultants and advisers in special subjects; a noteworthy feature was the agreed policy arrived at after regular conferences between the administrative and professional sides.

Low Sickness Rates

In each quarterly report I have had to repeat "Sickness rates remain low"; from June, 1944, until April, 1945, they averaged 23.6 per 1,000, which compares with 53.9 per 1,000 for the B.E.F. (1914–18) fighting in the same country. The reason for this very low rate needs critical examination by hygienists and statisticians, but my own suggestions are:

1. *General Management.*—The Force was carefully selected physically and part of it was selected psychiatrically. It was trained to a high pitch of fitness; both men and clothes were kept clean; food was generous in amount and water discipline was good.
2. *Infestation.*—In 1914–18 it was said that nearly half the sickness was due to infestation—trench fever and infected pyodermias, from either lice or acari. In the B.L.A. the louse was virtually abolished by personal hygiene and D.D.T., and scabies rarely became a problem, as prompt treatment with benzyl benzoate by the regimental medical officer was usually effective.
3. *Changed Conditions.*—We were spared long periods of trench warfare, although we had a dusty summer, a wet autumn, and a bitter winter.
4. *Good Fortune.*—There was no influenza pandemic.

Other Comparisons with the B.E.F. (1914–18).—We had four times as much jaundice and twice as much diphtheria; until April, 1945, the V.D. rate was just a little less; our incidence of enteric fever was 1/200, of cerebrospinal meningitis 1/4, and of pneumonia 1/6: these figures are computed on case rates per 1,000. Chemotherapy showed an improvement in case mortality: we had 1 death from cerebrospinal meningitis in 35 cases; in the B.E.F. it was 1.17%; our pneumonia mortality was 1% against 12.4%, while we had no deaths from dysentery against 0.6%.

Diarrhoeal Diseases.—In Normandy the incidence was high, and accounted for 31% of medical admissions. In the winter it still continued, and between 6 and 8% of medical admissions were diarrhoeal: its control is still imperfect.

Respiratory Diseases.—These constituted 32% of medical admissions from Jan. to March, 1945; there is a seasonal rise at this time of year, and living conditions had changed—houses instead of an open-air life. In other words, spacing was the only method of control of these droplet-spread diseases under the prevailing conditions, and it was not very effective.

General Comments on the Sickness Trends.—Much was achieved by fitness and cleanliness, by the eradication of the louse, and by the prompt treatment of scabies, while good water discipline and inoculations played an important part. Diarrhoeal diseases are but partially controlled, and droplet infections are almost uncontrolled: these facts are stressed to counteract complacency. The accompanying Table shows the varying incidence of certain diseases by quarters, expressed as percentages of 50,000 medical admissions.

Table showing Quarterly Incidence of Disease (Percentages of Medical Admissions)

Disease	July–Sept., 1944	Oct.–Dec., 1944	Jan.–Mar., 1945
Acute diarrhoea	31	8	6
Respiratory diseases	14	25	32
Infectious diseases	5	8·5	10
Skin diseases	18	15	16
Chronic rheumatism	4	6	3·5
Dyspepsia and ulcer	3	5	4
Acute infective hepatitis ..	1·5	3·1	4
Renal diseases	1·5	3	1·5
Malaria	11	2	1
Sciatica	1	1	1
Organic nervous diseases ..	1	1·5	1·5
Cardiovascular diseases ..	1	1	1

Phases of the Campaign

The campaign divided itself into three parts, each with its own problems; in each phase there were variations in seasons, living conditions, and prevalence of communicable disease in the civil population. Finally there were the problems of the civil side when Germany was overrun.

Phase 1: Normandy (June–Aug., 1944).—During the beach-head days of dust, flies, mosquitoes, and improvised accommodation (tents or foxholes) the prevalent disease was diarrhoea; it was christened the "Normandy glide," perhaps from the lessened urgency of its demands on Middle East standards. Many troops had come from malarious parts of Sicily and Italy, and their malarial relapses became a serious problem, as man-power was short. Weil's disease, although a very minor problem, made even jaundice interesting, while an outbreak of 80 cases of typhoid fever in one small headquarters mess exercised both hygienists and physicians. Droplet infection was negligible and the V.D. rate low.

Phase 2: The Low Countries (Sept., 1944, to March, 1945).—A wet autumn, a bitter winter, houses instead of open-air life for most, friendly and populous countries, and endemic diphtheria in the part of Holland then liberated—this was the background. Droplet infection became rife, and this would not have mattered had it been no worse than the colds we all got on going into houses; sore throats were prevalent, and each might be diphtheritic in view of the epidemicity of the disease. The negligible V.D. rate rose briskly, malarial relapses almost disappeared, but dysentery simmered constantly. The anticipated late autumn outbreak of jaundice did not materialize, but the incidence rose steadily.

Phase 3: Germany (April to July, 1945).—Although the Rhine was crossed in good weather the later spring and summer were wet; the troops again led a more open-air life. The disease problems were those expected, although dysentery did not become a big problem as in Normandy and sore throats still were very widespread. The V.D. rate continued to rise. Our own troops did not give us much anxiety, and even Weil's disease still remained where we had left it—in Normandy—although there were plenty of water in Holland and Germany and infected rats. Our chief worries were from civilian internees and liberated prisoners of war—typhus, starvation, and tuberculosis.

Malaria

About 30 men who had not been in malarious zones contracted malaria in Normandy; there were numbers of men harbouring gametocytes, and anophelines were identified in the Caen sector—this was not our main preoccupation. In the Force there were about 40,000 men who had served in Sicily and Italy. Many had had previous attacks of malaria, and relapses were anticipated; others had been infected late in the previous malaria season, and had their "delayed primary attack" in Normandy. About two-thirds of our cases were relapses and one-third were delayed primary attacks.

Before the invasion a rather alarming number of malarial attacks occurred in the training areas in the United Kingdom among the ex-C.M.F. contingent. An attempt was made to prevent further relapses by resuming suppressive mepacrine or by giving intensive courses of mepacrine for a week to men in the infected divisions. The effect on the relapse rate was negligible, and our final conclusion (which is widely held) was that the only way to cut down the relapse rate of B.T. malaria was to secure adequate treatment of each patient when he was actually in a relapse, and that pamaquin (plasmoquine) must be included in this treatment. Up to the middle of July, 1944, I estimated that there had been between 800 and 1,000 cases in Normandy; from then until the end of September there were a further 1,100 cases (11% of the medical admissions). The problem became an urgent one of man-power conservation. At first all cases had had to be evacuated to the United Kingdom, but from the middle of July the majority were treated in Normandy.

Treatment.—The first step had been to put malaria relapse in its right perspective—a trivial and short-lived illness. We decided on three treatments:

1. *5-day Course.*—This was a measure of expediency used in the early days with the object of getting men back to duty in about 7 days. Quinine bihydrochloride 30 gr. and pamaquin 0.03 g. were given concurrently and daily for 5 days.
2. *10-day Course.*—As soon as beds became available all relapses and delayed primary attacks had quinine–pamaquin for 10 days.
3. *21-day Course.*—If a man had three relapses in one season he was given the above course of quinine–pamaquin for 7 days, and then two-thirds the dosage for 14 days.

While the 10- and 21-day courses seem to be the best so far achieved, much has yet to be done to remove the problem of the B.T. relapse.

Acute Diarrhoeal Diseases

These were rife, but were mild on Middle East standards. The aetiology was not worked out on a large scale. Infection by the food-poisoning group seemed to be exceptional, and most cases of diarrhoea were dysenteric: this statement is based on discussions with many physicians and pathologists. Major R. W. Evans (personal communication), for example, examined 197 stools from consecutive diarrhoeal admissions in Normandy and isolated *B. dysenteriae* from 102 (Flexner 97, Sonne 4, Schmitz 1).

The supply of sulphonamides was lavish, and regimental medical officers had both sulphathiazole and sulphaguanidine, with instructions to treat all possible cases at unit level. Much man-power was thus saved. Of those admitted to hospital, and nearly always treated with sulphaguanidine, the average stay was about 7 days: this reflects the mildness of the infection, as my comparable Middle East figure was 17 days (Bulmer and Priest, 1943). No deaths occurred among Allied troops, but there were several among German prisoners of war treated by their own medical officers.

A condition which accounted for nearly one-third of medical admissions in Normandy, although relatively trivial and without fatalities, can hardly be dismissed after merely lauding its specific treatment. Can nothing be done to prevent it? Little has yet been accomplished except by the usual hygiene measures, which are of great importance and certainly reduce its incidence. In careful studies of isolated outbreaks in the U.K. many, if not most, have been traced to food-handlers who were carriers. It seemed to me justifiable to accept this mode of spread, and to recommend the periodic "sterilization" of food-handlers' stools by a week's course of sulphaguanidine. This was done in one key unit with good effects—a large-scale and controlled experiment was not practicable.

During the Normandy phase we were ignorant of the American work on chemoprophylaxis—the prevention of certain diseases by the continuous taking of sulphonamides: 1/2 to 1 g. of sulphathiazole daily during the dysentery season would be an interesting method with which to experiment under field conditions.

Typhoid Fever

In the autumn of 1944 an epidemic of typhoid fever affected 79 men from one small unit and one of the nursing sisters who attended them; the origin of the outbreak remains unsolved. It was, however, a serious one, as 11% died and complications and recrudescences were frequent. Jordan and Jones (1945) say of it: "Despite the fact that all the patients had been immunized against the enteric group of organisms the course of the disease was severe and unmodified." The efficacy of T.A.B. is not in dispute (our typhoid rate was 1/200 that of the B.E.F., 1914–18), but if patients are overwhelmed they will contract the disease, and apparently in an unmodified form.

Treatment remained expectant, but at a later date slight sensitivity of the typhoid bacillus to penicillin was demonstrated by Major R. W. Evans (unpublished), and several cases were treated very intensively with the drug without improvement in their condition.

Weil's Disease

A note has already been published on this subject (Bulmer, 1945). Buckland and Stuart (1945) re-examined our sera against further strains of leptospira, and found two which agglutinated *L. grippo-typhosa*—a form which is spread by Continental water-voles, and gives a brief brisk attack of Weil's disease without jaundice. Doubtless a number of our "short-term" fevers were due to this infection.

Diphtheria

Intelligence reports had warned us that diphtheria was endemic in Holland; we were apprehensive, as, apart from possible protection in childhood, neither British nor Canadian members of the Force had been immunized. When cases started to crop up it became evident that few medical officers had had much experience of diphtheria; owing to widespread immunization campaigns the disease had become much less common, and clinical opportunities during their student days had been limited. This applied even more to the Canadians, many of whom had never seen a case. They were soon to become very expert!

All medical officers were rapidly made "diphtheria-minded," and were asked to treat all suspicious sore throats at once on a clinical assessment. Very few cases were overlooked, and antitoxin was given very early. Naturally a great deal of it was given unnecessarily; but this did not matter—it was withholding antitoxin that we feared. The results were most creditable. My figures are liable to criticism, especially in the group called "clinical" diphtheria and not bacteriologically confirmed; nevertheless I was satisfied that the diagnostic error was not greater than 25%—many claimed it to be much less. I have notes of 3,000 cases and of 6 deaths—the figure for fatalities I know to be correct—this gives a case mortality of 0.2%.

The disease was on the whole mild, although there were a number of "gravis" infections and bull-necked types were not uncommon. Neurological complications were much less common than in the Middle East. We relaxed very considerably the strict nursing of diphtheria which is insisted upon in British fever hospitals: there were no ill effects, and the patients were much more comfortable.

Penicillin in Diphtheria.—This was used *as an adjunct* in the hypertoxic cases. Lieut.-Col. J. Bolton (personal communication) has some evidence to show that *C. diphtheriae* clears much more rapidly from the throat in penicillin-treated cases.

Convalescent Carriers.—If swabs were still positive on the 30th day the patients were transferred to a special wing of a hospital under Lieut.-Col. (now Brig.) R. E. Tunbridge, who had worked out a scheme of rehabilitation for these otherwise convalescent men. Tunbridge's studies (unpublished) on the effects of penicillin given locally in clearing carriers showed that it was not useful and that tonsillectomy remained the treatment of choice in the prolonged carrier.

Prevention.—Diphtheria is a dangerous disease; few victims are fit for duty under 6 to 8 weeks, and some are off for months with paralysis—the loss of man-power is therefore great. In future campaigns the problem need not arise if all troops are immunized on enlistment.

Typhus

The members of the Allied Forces had been protected against typhus by inoculation before D Day and had had a "booster" dose early in 1945; lousiness was uncommon, and D.D.T. was available as a dusting powder, and in solution for the impregnation of clothing. Typhus was known to be present in Germany among internees and forced-labour organizations, but it was not encountered in the mass until concentration camps such as Belsen and Sandbostel were uncovered: in them the Army medical services had to care for thousands of cases. There were some cases of typhus among released prisoners of war, and some of the British troops working in the concentration camps developed it; otherwise I am unaware of the occurrence of cases among military personnel. Protection and the anti-louse measures had proved most effective.

The disease as seen among internees was, on the whole, mild, and it was classical louse-borne typhus; the case mortality cannot be ascertained as many presumably died of starvation before the rash of typhus came out: in Belsen the case mortality from overt typhus was not high. After the internees had been deloused with D.D.T. there were very few secondary cases.

Effects of Inoculation.—In Belsen some British soldiers and some British medical students developed typhus; as they were all working in the filthy huts of the original camp, dust-borne spread seemed not only possible but likely. Among 21 such of whom I have notes there were no deaths—all had been inoculated. I have not complete notes of all the German personnel in Belsen who contracted typhus; of 25, many of whom I saw, 18 died—none had been inoculated. The series are not comparable, as there were differences in age, duties, diet, and living conditions. That typhus could kill the uninoculated is shown; that it did not kill the inoculated is satisfactory.

Starvation

Prisoners of War.—A number of cases of starvation were met with, as there had been a long period of under-nutrition, and often serious symptoms had been brought on by the forced marches from camp to camp as we advanced. There were few serious cases among British, Canadian, and United States troops, but very advanced emaciation was seen among other Allied troops, such as Russians and Poles. Our first problem was to try to get the newly released prisoner judiciously fed: serious, sometimes fatal, vomiting and diarrhoea had resulted from the mistaken kindness of their liberators. Full Army field service rations were ill tolerated; the secret of this early feeding is a soft, "pappy" diet. All prisoners fit to travel were flown back to the U.K.; those unfit were admitted to military hospitals in B.L.A. and rapidly improved on a simple gastric diet.

Civilian Problems.—Starvation was seen at its worst in civilians in Holland and in internees in Germany. I am unwilling to write on this subject, as it should be left to those who followed cases from day to day; it was unfortunate that the mass of material available for study by the R.A.M.C. was met with under conditions which made research and detailed scientific observations impossible, and it is doubtful whether anything but clinical observations will be published. I had many opportunities of observing the starving in Holland and in the German concentration camps (Belsen and Sandbostel) and camps for Russian prisoners of war—the sources of my information are too numerous to mention. I would make the following comments:

Clinical Features.—There were three types: wasting without oedema; oedema without wasting (rare); wasting with oedema. In Belsen, where starvation was acute and water scarce, *oedema* occurred in only about 6%; in Holland it seemed to be much commoner. Its cause is obscure, and there was little correlation with the level of plasma proteins. *Diarrhoea* was very common, and almost invariably present in the fatal cases; its cause, also, was obscure; dysentery bacilli were isolated in only about 15% of cases. We had assumed that it was dysenteric, and had provided large stocks of sulphonamides to treat it. Necropsy showed changes not unlike those seen in ulcerative colitis. Many cases were undoubtedly due to tuberculous enteritis. *Anaemia* was common: we had expected to find conditions resembling tropical nutritional anaemia, and had provided some liver extract, but investigation showed that both red cells and haemoglobin were equally reduced, and the blood picture suggested a simple marrow wasting. *Avitaminoses* of a clinically recognizable type were rare; perhaps they had been counteracted by the vegetarian diet—sometimes even raw grass was eaten—and by the use of potato peelings as a food. I saw two cases of pellagra at The Hague with Prof. J. Beattie, a few cases of polyneuritis, and a number of abnormal tongues, perhaps from lack of the B complex. Phrynodermia was common, but it may not be an avitaminosis. *Tuberculosis* was an alarmingly frequent sequel. *Gall-stone colic* was often seen, and gall-stones were found in most post-mortem examinations—possibly explained by dehydration.

Treatment.—*General:*—In mild cases a simple gastric diet suffices. In moderate and severe cases the best-tolerated foods were skimmed milk with glucose and the Bengal famine mixture (a gruel made with flour, sugar, salt, and water), and later the dietetic ladder was ascended. Three compound vitamin tablets were given daily. Casein and protein hydrolysates had been prepared on a big scale, and controlled experiments were conducted in Holland under the direction of Prof. Beattie: they could be given orally, by nasal tube, or intravenously. In Belsen they were used on a small scale; but they were most nauseating by mouth. Patients had to be persuaded to take their drinks, and extensive nasal feeding was impracticable; their superiority over the simpler diets has not been established. *Oedema:*—This usually disappeared with a good diet. If it was very severe salyrgan intravenously was effective and seemed harmless. *Diarrhoea:*—As the cause was not clear, rational treatment was out of the question. The multiplicity of treatments found to be effective suggests that none was specific. *Intravenous Plasma:*—At Sandbostel Camp Capt. A. R. Blower carried out a most extensive experiment with plasma; he used 1,196 pints—an average of 5.1 pints per patient. His conclusions (personal communication) were that it had no effect on diarrhoea; it gave good results in severe wasting; and in oedema the results were inconclusive.

Penicillin

We had ample supplies of penicillin, and every opportunity was seized of studying its use in medical as opposed to surgical conditions. Owing to its non-toxicity and its action on a wide range of organisms, it would replace sulphonamides were its method of administration by repeated injection not so impracticable except in hospitals: the sulphonamides remained our sheet anchor in acute infections except from resistant organisms. Penicillin's greatest value to a fighting army was in reducing the time spent in hospital for simple ailments. The Adviser in Venereology (Lieut.-Col. D. J. Campbell) was able to reduce the time of treatment for gonorrhoea to 24 hours, and for syphilis to a little over a week if treated early in the primary stage. In simple pyodermias the Adviser in Dermatology (Lieut.-Col. F. F. Hellier) exploited its use to the full, even in minor medical units with the field force, and saved countless man-days. In ulcerative gingivitis its local application seemed to be specific, and the penicillin tablet should be the simple answer to this common ailment.

In the serious infections, where our object was to save life and not man-days in hospital, it proved invaluable in staphylococcal septicaemia and staphylococcal pneumonia. In pneumococcal pneumonia it was not better than sulphonamides. In meningococcal meningitis it proved to be curative if given intrathecally; but the many lumbar punctures needed make its use objectionable, and there is the danger of introducing resistant organisms into the theca. In Weil's disease it is of value in some strains if given very early. In acute diphtheria it is a useful adjunct to adequate antitoxin, and may clear the throat of bacilli more quickly than the average time taken.

Conclusion

I fear I have done scant justice to the team of British and Canadian physicians with whom it was my privilege to be associated; this is their work, and I have made myself their mouthpiece. They, working for the most part under improvised, difficult, and sometimes dangerous conditions, maintained a high standard of medicine, and a standard of acute medicine which I know I shall not again see. I regret that individual acknowledgment is possible only in a few instances.

The Canadian side, with its happy blend of British and American medicine, was always an inspiration, and I would thank Col. Murray Baird, R.C.A.M.C., their Consulting Physician, for his constant help. Finally, my thanks are due to the Director of Medical Services, 21 Army Group, Major-Gen. E. Phillips, for permission to publish this article, but more especially for his consistent support of, and constant sympathy with, the clinical side.

E. C. Ross Couper (*Arch. Dis. Childh.*, 1945, **20**, 117), from a study of twenty cases of various infections in infants, concludes that penicillin has a useful part to play in parenteral infection in infancy, but much further investigation is needed.

ESTIMATION OF SERUM PROTEINS BY THE LINDERSTRÖM-LANG GRADIENT

BY

HANS HOCH, Ph.D.Vienna
Freedom Research Scholar

AND

JOHN MARRACK, D.S.O., M.C., M.D.
Professor of Chemical Pathology in London University

(From the Hale Clinical Laboratory, London Hospital)

The gradient method described by Jacobsen and Linderström-Lang (1940–1) affords a very quick and convenient means of measuring the specific gravity of serum and hence of estimating the concentration of protein in serum, as only the drop is needed. In this method a light and a heavy mixture of kerosene and bromobenzene are prepared. The lighter mixture is superposed on the heavier in a glass cylinder and the column of fluid is stirred. A zone is formed in which the specific gravity decreases with the height. The specific gravity of serum introduced into the column is estimated by comparison with the position taken up by drops of salt solution of known specific gravity. The apparent specific gravities found by this method differ from the true specific gravities, although the difference is less than that found in the copper sulphate method (Hoch and Marrack, 1945). This difference is reduced if chlorobenzene is used instead of bromobenzene.

Method

As the journals in which the preparation of this gradient is described are not available in all libraries, details of this preparation, with slight modification, are here given.

The Gradient.—Two mixtures of chlorobenzene (spec. grav. $S^{20}_{20}=1.109$) or bromobenzene (spec. grav. $S^{15°}_{15°}=1.499$) with kerosene (spec. grav. approximately 0.80) are prepared so that their specific gravities $S^{t°}_{t°}$ ($t°$ = room temperature) are approximately equally spaced about the midpoint of the range required. The specific gravities of these mixtures should be approximately 0.04 above and 0.04 below that of the midpoint of the range of specific gravities required. For example, two mixtures prepared by mixing chlorobenzene and kerosene in the ratio of approximately 7.5 and 0.69 by volume had specific gravities ($S^{24°}_{4°}$) 1.064 and 0.982. At the midpoint of the gradient prepared with these mixtures the specific gravity $S^{24°}_{4°}$ was 1.023 and $S^{24°}_{24°}$ was 1.0257, corresponding to a concentration of protein in serum of 6.75 g. per 100 ml.

About 100 ml. of the heavier liquid is placed in a wide graduated cylinder (e.g., a 500-ml. measuring-cylinder which has been cut off at the 250-ml. mark) and the same amount of the lighter liquid is superposed by letting it run in slowly down a glass rod which touches the wall of the cylinder near the surface of the liquid. The two liquids are then mixed by moving a glass rod, bent at the lower end, up and down in the column with continued rotation until streaks (schlieren) appear at the bottom and top of the column. The gradient should then be tested with two drops of standard solutions, specific gravity 1.020 and 1.030. The distance between them should be 4 to 5 cm. The apparent specific gravity of a drop can be read with an accuracy of at least ± 0.0002.

As emphasized by Linderström-Lang (1938), saturation with water is essential. After the gradient is made up a set of 10 drops of the standard solutions should be left suspended in the column for at least a day before it is used. The cylinder should be kept in a water jacket in order to prevent rapid changes of temperature.

Standard Solutions.—The series of copper sulphate solutions with specific gravities differing by 0.001 prepared from a stock solution ($S^{24}_{24}=1.1000$; 159.6 g. in 1,000 ml. at 24° C.), as described by Phillips, van Slyke, *et al.* (1944, 1945), can be used. A series of drops covering the range of specific gravities anticipated is introduced into the column by the method described for serum. Fresh drops of the standard solution should be introduced if the old ones have been disturbed on removing a batch of drops of serum.

Procedure.—With a narrow pipette, attached to a rubber bulb, take up between 5 and 15 c.mm. of serum. Bring the point of the pipette about 3 mm. below the surface of the fluid in the cylinder. Blow the serum out gently so that it does not leave the point of the pipette until the pipette is withdrawn from the surface of the fluid. A slight positive pressure should be maintained throughout. Drops of 5 to 15 c.mm. are recommended instead of 1 c.mm. as used by Jacobsen and Linderström-Lang (1940–1), in order to increase the rate of fall and, in the case of serum, to delay solution of chlorobenzene or bromobenzene. Readings should be taken at the centres of the drops, with precaution to avoid errors due to parallax. Every measurement is referred to the position of the nearest drops of standard solution by means of linear interpolation at the time of reading. Although the distances between two pairs of standard drops that differ in specific gravity by equal amounts may be found to be equal, it is possible that there may be occasional irregularities in the gradient; but the error in the estimate of specific gravity of the serum is not likely to exceed 0.0005. The level of the drops should be read 10 minutes after their introduction. This time was chosen because (*a*) it exceeds the time (2 minutes) required by drops of the standard solution to reach equilibrium to within a specific gravity of 0.0001, and (*b*) in this time the increase of specific gravity of the drop of serum, due to solution of chlorobenzene or bromobenzene, becomes so slow that no appreciable change in its level occurs while the reading is being taken. Estimations can be made on several sera before the drops are removed.

Removal of Drops.—Moisten a piece of filter-paper and wrap it round the lower end of a long thin glass rod. Bring this in contact with the drops, which will adhere to the paper. After removal of the drops the gradient should not be used again for 30 minutes.

98	1·0257$_5$	1·0258$_0$	0·0000$_5$	0·02
		Average difference:	+0·0001	0·06

* Corrected to 24° C. by applying −0·00005 per ° C.

† Measured between 19° and 22·5° C., uncorrected for temperature; the extreme correction would not exceed 0·00005.

‡ This large difference was probably caused by the error in the determination by direct weighing.

Changes with Time.—The mixture gradually becomes uniform throughout; changes in two weeks may be appreciable.

Recovery of Reagents.—The chlorobenzene or bromobenzene can be separated from the kerosene, in a state fit for use in making a fresh gradient, by distillation at normal pressure. Unless the distillation is carried out under reduced pressure, part of the kerosene must be replaced by fresh material.

Effect of Temperature

One of the advantages of the copper sulphate and gradient methods, as compared with direct weighing and the falling-drop method, is that serum is compared with aqueous solutions whose coefficients of expansion differ little from those of sera. If the slight effect of temperature on the difference of solubilities of chlorobenzene in serum and copper sulphate solution is disregarded, the effect of temperature is the same as that in the copper sulphate method: the error in the calculated concentration of protein due to change of temperature up to 34° C. or down to 14° C. will not amount to more than 0.04 g. per 100 ml.

Effect of Solution of the Halogen-benzene in Serum

The apparent specific gravity of serum in the chlorobenzene gradient is higher than that found by weighing in a pyknometer (Table I), and the apparent specific gravity in the bromobenzene is higher than in the chlorobenzene gradient (Table II). These differences are apparently due to preferential solubility of the halogen-benzene in the serum. The solubility of bromobenzene in water is 0.045 g. per 100 ml.; the increase of the specific gravity of a drop of water owing to saturation with bromobenzene is about 0.0002. The halogen-benzenes are presumably much more soluble in serum than in water owing to the lipids in the serum. As the difference between the specific gravities of bromobenzene and serum is much greater than that between those of chlorobenzene and serum, a small excess in the amount dissolved in serum over that dissolved in the standard drops has a considerably greater effect in the case of the bromine compound. The specific gravities of the drops increase as the serum becomes saturated with the halogen compound; hence the differences between the specific gravities found in the bromobenzene and the chlorobenzene gradients are greater at 60 minutes after the drops are introduced than at 10 minutes. After the first 10 minutes the increase of specific gravity in the chlorobenzene gradient amounts to only 0.0002 in 50 minutes.

The difference in the solubility of the two compounds is illustrated by the behaviour of drops of different sizes in the two gradients. Within a short interval two pairs of drops of size about 50 c.mm. and 1 c.mm. were dropped into a chlorobenzene and a bromobenzene gradient. During the first 10 minutes in the bromobenzene gradient the small drop sank much below the level of the large drop; while in the chlorobenzene gradient the two drops were nearly level. After 6 hours the small and large drops were exactly level in both gradients.

Reproducibility and Accuracy

The readings obtained when two drops of the same serum were added to the same gradient in immediate succession were always identical. The specific gravities found using different gradients, or the same gradient at different temperatures, always agreed within 0.0004 and usually within 0.0002.

The concentrations of protein in serum calculated (N × 6.25) from estimation of nitrogen by the Kjeldahl method were taken as the true concentrations. The values of K and A in Equation 1

$$P=K\,(S-A)$$

(where P is the concentration of protein in g. per 100 ml. and S the observed specific gravity), calculated statistically, are given in Table III. For convenience in calculation, in practice, the equations adopted were: Equation 2 for specific gravity found by direct weighing:

$$P=365\,(S-1.007)$$

and Equation 3 for apparent specific gravity found by the chlorobenzene gradient:

$$P=361\,(S-1.007).$$

The readings can also be made with fair accuracy 40 to 60 seconds after the introduction of the drop. If this is done the value of A should be 1.0069.

Using these equations, the agreement between the results obtained by direct weighing or the chlorobenzene gradient on the one hand and by the Kjeldahl method on the other is remarkable in the normal sera and satisfactory in others. As with the copper sulphate method, the average values found by specific gravity methods in sera from women during pregnancy and after delivery tended to differ in opposite directions from those found by the Kjeldahl method. This difference, which may be due to the higher concentration of lipids in the serum during pregnancy, is being studied further.

The "normal" sera were obtained from blood donors at the end of bleeding, after lying down for not less than 10 minutes; the concentrations of proteins found may therefore be abnormally low. The other subjects were bled with precaution to avoid stasis.

Since Table III was completed we have received a serum from a patient with extreme hypoproteinaemia, probably due to faulty nutrition. The concentrations of protein found were: Kjeldahl, 2.54 g./100 ml.; copper sulphate method (Equation 4, P=364 (S−1.006), Hoch and Marrack, 1945), 2.55 g./100 ml.; chlorobenzene gradient, 2.64 g./100 ml. The equations proposed therefore give satisfactory results when the concentration of protein in serum is very low.

[As this paper was going to press we received an article by Lowry and Hunter (*J. biol. Chem.*, 1945, **159**, 465) which gives a full description of the gradient method, using bromobenzene, with a discussion of its accuracy.]

Summary

The gradient method of Linderström-Lang is a convenient and rapid means of estimating the concentration of protein in serum.

The apparent specific gravities found by this method are higher than the true specific gravities. This difference is attributed to preferential solution of the halogen-benzene in the serum; it is less if chlorobenzene is used in the place of bromobenzene. Within moderate limits the effect of temperature is negligible.

Using chlorobenzene, satisfactory and consistent measurements of the concentration of protein are obtained.

LIVER FUNCTION IN INFECTIVE HEPATITIS GAUGED BY HIPPURIC ACID SYNTHESIS TESTS*

BY

M. R. POLLOCK, M.B., B.Ch.

Up till recently the hippuric acid synthesis test has been employed mainly as an indication of liver damage in isolated instances, particularly in the differential diagnosis of jaundice. In the present work the test has been used serially in an attempt to follow the course of liver damage in cases of infective hepatitis. Although there are many complications, both theoretical and practical, in the interpretation and analysis of the results of this test, it was decided that it was probably the most reliable of known guides to liver function, particularly in the presence of jaundice. Moreover, one of the more serious objections to the test—the wide "normal" range of figures obtained in healthy persons—does not apply when following liver function by serial tests in the same individuals.

Methods and Technique

Cases of infective hepatitis were admitted to hospital usually within three days of the appearance of jaundice. In most instances the serum bilirubin and hippuric acid synthesis were first estimated the next morning. The serum bilirubin was subsequently estimated (Malloy and Evelyn, 1937) twice weekly until the peak value was passed, and thereafter once a week until discharge; estimations were not always done on the same day as the hippuric acid test, and many of the values on which the accompanying Table is based have been obtained by interpolation between the nearest figures before and after the date of the test. The second hippuric acid test was performed usually just under a week after admission, and a third and final test was done a week to 10 days before discharge. The method used was the intravenous modification of Quick (1939), in which 1.77 g. of sodium benzoate was injected intravenously and the urine collected after one hour. The amount of hippuric acid thus excreted was estimated by the technique recommended by Weichselbaum and Probstein (1938), and expressed in terms of the quantity of sodium benzoate detoxicated. The present series includes 81 cases, 46% of which were admitted with rising serum bilirubin. Patients who developed relapses have been excluded.

Results

The results are recorded in the accompanying Table, which is so arranged that a direct comparison can be made between the hippuric acid results and the serum bilirubin concentration.

---

* A report to the Medical Research Council.

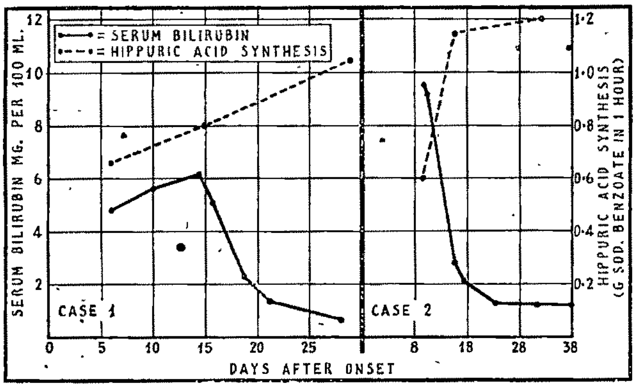
Cases have been divided into two main groups (A and B) according to whether they were admitted with rising or with falling serum bilirubin. These groups have been further subdivided arbitrarily into four roughly equal subgroups (1, 2, 3, and 4) according to the maximum recorded serum bilirubin values. The main points can be summarized thus:

(i) The hippuric acid synthesis (H.A.) appears to reflect the severity of the attack and the stage of the disease rather than to be directly correlated with the serum bilirubin concentration. For instance, there is a significant difference (Difference/Standard Error=2.84) between the initial H.A. values in Subgroups 1 and 2, indicating a correlation between H.A. synthesis and severity of attack fairly early in the disease. There is also a significant difference (D./S.E.=2.33) between the initial H.A. values in Subgroups 1 and 3, although in this case the bilirubin concentrations are roughly equal; in Subgroup 1, however, the serum bilirubin is rising, and in Subgroup 3 falling; it is not surprising, therefore, that liver function in Subgroup 3 is better than in Subgroup 1. The difference applies only to the more severe cases, and is not apparent in Subgroups 2 and 4.

(ii) There is a considerable increase in H.A. values during the first 6 days in all groups. Even in Subgroup 1 the mean rise (0.126±0.0125) is appreciable. The rise in Group B (0.325) is well over double the rise in Group A (0.139), consisting of cases admitted earlier in the disease, and the difference between the improvements in the two groups is highly significant (D./S.E.=3.91). It is of interest that this improvement in H.A. synthesis during the first week after admission occurs despite an increase in serum bilirubin. In Subgroup 1 it can be seen that there is a large mean rise of nearly 3 mg. per 100 ml. in serum bilirubin over the same period as the improvement in H.A. synthesis.

(iii) There is little difference between the groups in the mean H.A. synthesis before discharge. With the exception of Subgroup 1 this final test was performed, on an average, at the same interval after admission in all groups. Although Subgroup 1 is not strictly comparable with the other groups in this respect, there is no indication that the more severe attacks have produced any permanent liver dysfunction.

The course of H.A. synthesis and of serum bilirubin concentration in two patients are shown in the accompanying Chart, as illustrating the types of case most often met with. They represent much the same picture as would be obtained from a study of the average figures recorded in the Table.



Serum bilirubin values and hippuric acid synthesis in two "typical" cases of infective hepatitis

Possible Objections to Use of Test

(*a*) *Renal Damage.*—Although there is no reliable evidence to suggest that kidney damage occurs in any but the most severe cases of infective hepatitis, and Schwei and Quick (1942) have shown that damage to the kidney would have to be considerable before H.A. excretion became a limiting factor in the liver function test, it was thought advisable to test the renal function of a sample of cases in order to obtain first-hand evidence. Blood-urea concentrations and urea-clearance tests were therefore done on 12 unselected cases on admission. In all instances results were well within normal range. The mean blood urea was 26.4 (±1.74) mg. per 100 ml., and the mean urea clearance was 159% of average normal, the lowest value being 97%. It does not appear likely, therefore, that renal damage, if it occurs at all, is sufficient to invalidate the use of the H.A. test in infective hepatitis.

(*b*) *Changing Protein Intake.*—It has been shown by Probstein and Londe (1942) that H.A. synthesis can often be increased by ingesting large quantities of glycine. Many patients in this series suffered from anorexia on admission, and in most cases their appetite, and therefore their intake of protein, increased during the first week in hospital. It was calculated that, on an average, the protein intake per day increased from 60 g. (on admission) to 120 g. (on discharge), and a large proportion of this increase probably occurred during the first week. It was therefore considered possible that at least part of the improvement in H.A. synthesis found to occur in most cases of infective hepatitis after admission to hospital might be a reflection of improvement in appetite rather than in liver function. It was accordingly decided to investigate the effect of a severe reduction in protein intake on H.A. synthesis. Twelve convalescent patients were tested shortly before discharge—i.e., at a time when liver function might be considered to be constant or at least not deteriorating—by performing H.A. tests immediately before and after four days of a diet containing no milk, meat, or eggs and very little bread. This entailed a protein reduction from at least 120 g. a day to between 20 and 30 g. a day. The mean H.A. synthesis dropped by 10% from 1.00 to 0.90—a difference of −0.10 (±0.035). However, three patients actually showed a slight increase in H.A. synthesis after the diet. Since the conditions in this experiment are not and never could be really comparable with those pertaining to patients at the height of the disease, it is not possible to draw any hard-and-fast conclusion. The drop in protein intake of nearly 100 g. was possibly rather severe and certainly more than the average increase during the first week in hospital; and there is at present no means of knowing the relative effects of big changes in protein intake on H.A. synthesis of patients with different degrees of liver damage. It is not felt, therefore, that this difference in H.A. synthesis is great enough to invalidate the main conclusions based on our figures, although the results should, on this account, be treated with due reserve.

Discussion

These results show that in most cases there was a progressive improvement in liver function, as judged by the H.A. test, from the time of admission to hospital, although initially in nearly half of them the serum bilirubin concentration and jaundice were actually increasing. The H.A. synthesis was to a large

Mean Values of Serum Bilirubin and Hippuric Acid Synthesis during the Course of the Disease in 81 Cases of Infective Hepatitis

Serum Bilirubin Group	No. of Cases	On Admission		First Week after Admission			Before Discharge

H.A. = Hippuric acid synthesis in terms of grammes of sodium benzoate.

extent correlated with the severity of the attack and the stage of the disease, but only partly, and indirectly, with the serum bilirubin concentration.

It is possible that the apparent dissociation of bilirubin excretory function and H.A. synthesis might be explained by the fact that bilirubin is being formed in the body at an approximately constant rate, and that the efficiency of the liver is therefore to be judged by the amount of bilirubin excreted each day rather than the concentration in the serum. In other words, so far as bilirubin excretion is concerned, liver function should be gauged by the rate of rise or fall of the serum concentration; it is then clear that even a rising serum bilirubin might be associated with an improving excretion, so long as the rate of rise was diminishing. This is of course an over-simplification of the problem, since it does not take into account the excretion of bilirubin into the urine. The main principle, however, still applies whatever complicating factor is introduced, and may be enough to account for the apparent dissociation of function referred to above—without, of course, being evidence against such dissociation occurring in other respects. It also, perhaps, contributes to an explanation for the oft-repeated but perplexing observation that, in infective hepatitis, the appearance of jaundice frequently coincides with clinical improvement.

The present work has shown that H.A. synthesis was already improving on the patient's admission to hospital, and the final conclusion which seems to be justified is that maximum liver damage occurs in most cases before admission. This is consistent with the finding previously reported (Pollock, 1945) that liver damage is present in the pre-icteric stage some time before the serum bilirubin rises above normal and often several days before the onset of jaundice.

The practical application of this conclusion is that in order to demonstrate satisfactorily the effect of specific treatment in the average case it is preferable that it be started before the liver has begun to improve spontaneously—in effect this means before jaundice appears. Every effort was made to arrange for admission of our patients to hospital as soon as possible after the onset of symptoms; but, even so, only three were admitted in the pre-icteric stage, and it is unlikely that speedier admission will be achieved until there is some outstanding improvement in methods of early diagnosis. The problem of treatment of infective hepatitis depends, more than in most diseases, upon accurate diagnosis in the initial stages.

Summary

The course of liver damage in 81 cases of infective hepatitis has been followed by the use of serial hippuric acid synthesis tests.

The ability to synthesize hippuric acid bore some relation to the severity of the attack and to the stage of the disease, but was only indirectly related to the serum bilirubin level.

In most cases there was progressive improvement in hippuric acid synthesis from the time of admission to hospital, even though it was often associated with a rising serum bilirubin and increasing jaundice.

It is probable that maximum liver damage in this disease most commonly occurs before the patient is admitted to hospital. Specific treatment is therefore not likely to have any striking success unless begun in the pre-icteric stage.

Sir John Fraser, presiding at a meeting of the technical committee of the Scottish Blood Transfusion Association, reported that in the quarter ended Sept. 30 last the demands of the hospitals for blood and plasma had, for the first time, exceeded the supply of blood obtained from donors. Fortunately, Sir John said, the regional services had sufficient reserves to meet this contingency. There had been a falling off in donor attendances since the end of hostilities—a fact which gave rise to some concern in view of the continuing and increasing demands of the hospitals, particularly the maternity hospitals. During the quarter 6,986 bottles of blood were obtained from donors, as against 11,946 in the preceding quarter; and, but for reserve stocks, this would have been insufficient to meet the 3,934 bottles of blood and 2,937 bottles of plasma supplied to or reserved for the hospitals. An increase in the use of plasma by hospitals was reported at the meeting—a circumstance emphasizing the great need for new blood donors.

MANAGEMENT OF RECENT FRACTURE-DISLOCATIONS OF THE CERVICAL SPINE

BY

A. N. GUTHKELCH, M.Ch., F.R.C.S.
Capt., R.A.M.C.; Graded Neurosurgeon

(From a Military Hospital for Head Injuries)

The treatment of fracture-dislocations of the cervical spine by continuous skull traction (Crutchfield, 1933) is well enough established for a detailed discussion of its justification and indications to be unnecessary (but see Key and Conwell, 1937). Descriptions, however, of the practical details of the method vary considerably. The present communication is an attempt to combine various suggestions into a scheme of treatment which, so far as is possible, shall be simple, efficient, and comfortable to the patient.

Application of Traction

Reduction of a fracture-dislocation of the cervical spine involves both traction and extension (Watson-Jones, 1943). These can be achieved simultaneously, by an upward pull applied to the skull on a plane anterior to the atlanto-occipital joint. The anterior longitudinal ligament of the spine is thus tautened, and extension of the cervical intervertebral joints follows. This effect has been secured by traction on the zygomatic processes, but that has the disadvantage that extension of the head tends to proceed until the skin of the front of the neck is taut. In this position swallowing is difficult enough for the normal individual; when further impeded by dysphagia of medullary origin or by a large retropharyngeal haematoma it becomes impossible. On the other hand, if the calliper is placed directly above the pinna—i.e., vertically above the atlanto-occipital joint (as recommended by McKenzie, 1935; Barton, 1938; Watson-Jones, 1943)—the force causes traction alone without extension.

Hoen (1936) proposed to place the point of traction slightly more anteriorly, which is mechanically sound. He preferred to use 18- or 20-gauge stainless-steel wire, sinking two pairs of burr-holes in the skull near the midline and running wires through the extradural space between them. This method leaves the sides of the patient's head clear of projecting apparatus and therefore allows him to be turned more easily; the only objection is that the intervening bridge of skull has been known to break during the period of traction. In the series of cases on which this paper is based callipers or steel wire were used as they happened to be available.

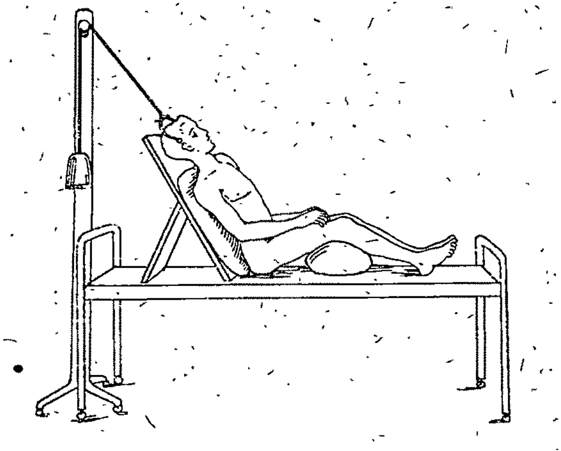
Counter-traction

Counter-traction is made by the friction of the patient's body against the mattress on which he lies, and a gravitational component may be added by raising the head of the bed. This latter also reduces the thrust of the abdominal viscera on the patient's diaphragm and his liability to pulmonary congestion and pneumonia. When abdominal distension is severe, as is not uncommon, raising the head of the bed even as much as two feet may not suffice to prevent respiratory distress. McKenzie (1935) illustrates a case of fracture-dislocation, evidently not complicated by spinal cord damage, which was nursed in the sitting position. In this position the upward thrust of the abdominal viscera is minimal and the patient can look round at others in the ward or read without recourse to mirrors or special apparatus. Further, his head is in the most natural position for the act of swallowing. I found that McKenzie's method can equally well be applied to cases with cord lesions.*

Management of the Case

In the method here described the point of application of traction is kept slightly anterior to the pinna so as to maintain extension, and the patient is nursed in the sitting position. The apparatus required has been simplified to the degree demanded by Service conditions. The bed is prepared as follows:

A stout post is lashed to the middle of the upper end and a wooden back-rest is laid at an angle of 60° on its upper half. Attach to the post a pulley at such a height that traction can be made approximately along the line of the rest. Have ready not less than 30 lb. of weights and plenty of sash-cord. I have not had to use more than 30 lb. in reducing any fracture-dislocation seen within the first three days. In a case a couple of weeks old 60 lb. has been required. Now lower the back-rest and cover enough of it with pillows to support the patient's trunk, but not his head or neck. An air ring is desirable for the buttocks and a "donkey" at knee level. On admission to the ward before reduction the patient is lifted supine on to the bed; his head and neck, being clear of the pillows, will be maintained in a position of extension.



The head-tractor can be applied without further movement. If callipers are used, burr-holes should be made in the skull, under local analgesia, at a point not more than one inch anterior to the external auditory meatus and slightly above the temporal crest. Traction so applied will not over-extend the head. When the tractor is in position the surgeon steadies it while assistants raise the back-rest to an angle of about 60° with the bed. At first 18 lb. of traction is applied (see diagram).

A portable x-ray apparatus is now brought to the bedside. If in half an hour 18 lb. has produced no radiological change, the weight should be increased by 4 lb. and the increase repeated as often as necessary. Once the reduction begins it often progresses to completion within a matter of minutes rather than hours, and when it is complete the tractive weight can be reduced to 8–12 lb. without fear of redisplacement. If further extension of the spine seems necessary it can be provided by putting additional pillows under the patient's back. At this stage, too, it is desirable to see that the patient is reasonably comfortable and can swallow. If not, a slight reduction in the weight may help. The final radiograph should be taken not sooner than 30 minutes after heavy traction has been discontinued.

Traction at the 8–12 lb. level must continue for at least three weeks, during which it is desirable to check the position of the fracture radiologically every few days. After that time the weight can usually be gradually reduced, and in a further week or ten days, if the reduction is radiologically stable, a Minerva plaster jacket can be applied and the patient allowed up, provided no complicating spinal cord lesion is present.

Nursing care during the period of traction is not more difficult than after a major abdominal operation. Although the patient cannot, of course, be turned completely on his side, sufficient changes in his position to prevent the development of pressure sores are readily made. If they should occur, which in my series they did not, the patient could at once be restored to the horizontal position and nursed on his sides for a time. There should be a constant thickness of pillows behind the back, for on the whole the less the cervical spine is extended, the heavier the traction that must be applied to it in order to maintain reduction of the fracture.

In cases presenting complete spinal cord lesions on admission the early mortality rate is very high, and when a complete lesion shows no sign of recovery within fourteen days it can be assumed to be permanent. Once this is established the nursing care of the patient and his comfort are all that need be considered; the fracture is unimportant. However, the method described here has been continued after this time because it provided a maximum of comfort.

Results and Discussion

The series of cases treated by this method is small—seven in all. Four others have been treated by the same method in Prof. Geoffrey Jefferson's neurosurgical service at the Manchester Royal Infirmary. Deaths numbered four—all in cases of complete cord lesions. Such deaths may be regarded as inevitable. The other cases gave no cause for anxiety at any time, and no difficulty was experienced in maintaining a satisfactory reduction of their fracture-dislocations. In two cases with partial cord lesions which developed severe abdominal distension the benefits of the sitting position were apparent from their comparative comfort. Respiratory embarrassment (of which I have seen several distressing examples in cases nursed flat, even with the head of the bed amply raised) was not a feature. In the patients who died from ascending haematomyelia with medullary failure there was never any appearance of "fighting for breath"; respiration appeared adequate until the cardiovascular centres were already grossly affected. Artificial respiration by mechanical means must occasionally find a place in treatment, though when it is still necessary after reduction the patient is unlikely to survive for more than a few hours. But if the lesion is from the beginning compatible with life the patient needs only the optimum conditions for respiration and he will not die of a pulmonary complication. These conditions, together with other advantages, may be derived from treatment in a sitting position.

Summary

Some advantages and disadvantages of the method of treatment of fracture-dislocations of the cervical spine by continuous skull traction are considered, and the theoretical basis of the treatment is discussed.

It is suggested that it is an advantage to nurse the patient in a sitting position. Practical details are given and the experiences of a small series of cases mentioned.

My thanks are due to Lieut.-Col. L. S. C. Roche, *M.C.*, R.A.M.C., commanding a military hospital for head injuries, for permission to publish this paper, and to Prof. Jefferson for permission to mention the cases treated in his service.

THE THERAPEUTIC EFFICIENCY OF ULTRA-VIOLET-LIGHT APPARATUS

A COMPARISON OF TESTS

BY

B. C. ELLIOTT

Fl. Lieut., R.A.F. Electromedical (Research and Servicing) Unit, Chessington

The present investigation, undertaken at the direction of the Director-General of Medical Services, Royal Air Force, set out to determine the relative accuracy of commercial methods of measuring the therapeutic output of ultra-violet-light apparatus, as compared with laboratory techniques. Ultra-violet-light apparatus is widely used throughout the Royal Air Force, both for the treatment of pathological conditions and for its general tonic value—as, for example, in the case of aircrews engaged on night operations. It was therefore considered essential to ensure that the means used for testing the therapeutic activity of the output of U.V.L. apparatus were accurate within clinical limits.

Spectral Requirements for Ultra-violet-light Therapy

First it may be desirable to review briefly the nature of the frequency spectrum produced by commercial U.V.L. apparatus, and the spectral requirements for U.V.L. therapy. The spectrum of the mercury atom has a number of emission lines of radiation between 10,140 A.U. and 1,849 A.U. The longest of these (10,140 A.U.) falls in the infra-red range; others (5,790 A.U. to 4,050 A.U.) are visible, while a powerful group occurs in the "near ultra-violet" around 3,650 A.U. In the mid and far ultra-violet, strong mercury lines are found at 3,130, 2,967, 2,537, and 1,849 A.U. The relative intensities of these wave-lengths, and others less powerful, as emitted by a particular type of mercury-vapour-lamp, are a function of its design.

It is generally accepted (Laurens, 1933 ; Blum, 1944 ; Osborne and Holmquest, 1944b) that the therapeutic action of U.V.L. is dependent chiefly upon radiation of wave-lengths less than 3,200 A.U. ; for example, the mercury line at 2,967 A.U. has antirachitic properties (Forsythe and Adams, 1944a), while that at 2,537 A.U. is highly bactericidal (Forsythe and Adams, 1944a ; Osborne and Holmquest, 1944a). The chief value of the longer 3,650 A.U. group is in the diagnosis of fungous infections by fluorescence.

From the foregoing it is seen that a substantial proportion of the energy emitted by a mercury-vapour lamp has little therapeutic action, and the importance of distinguishing between active and relatively inactive radiation becomes apparent.

Methods of Measurement

Apart from laboratory techniques, two practical methods of detection and measurement of therapeutic ultra-violet radiation present themselves. These employ respectively the barrier-layer photovoltaic cell and the vacuum or gas-filled photo-emissive cell. The former develops a small voltage, while the latter emits electrons and becomes conductive, when subjected to radiation. Accordingly the indicating instrument used with the photovoltaic cell takes the form of a sensitive low-resistance microammeter connected directly across the cell; the photo-emissive cell, on the other hand, requires a source of direct voltage for its operation. It is customary to use a load resistance in series with the photo-emissive cell and its source of supply; variations in potential across this load are applied to the input of a suitable D.C. amplifier, in whose output circuit the indicating instrument (milliammeter) is connected.

The response of barrier-layer cells and photo-emissive cells varies widely with the wave-length of the incident radiation and the composition of the sensitive surface; it is therefore necessary to choose a cell having a suitable spectral characteristic for the measurements involved. The copper-oxide barrier-layer cell has a spectral sensitivity very different from that of the eye (Bowen, 1942b), and is therefore unsuitable for direct measurement of ultra-violet radiation. It can, however, be so used in conjunction with a suitable fluorescent screen, which converts the incident ultra-violet radiation to a longer wave-length within the range of sensitivity of the cell (Bowen, 1942d). Cadmium or sodium photo-emissive cells, on the other hand, have suitable characteristics for direct measurement of ultra-violet radiation. Of these types, the cadmium cell, having optimum sensitivity between 2,500 A.U. and 3,000 A.U. (Bowen, 1942c), is the better suited for measurement of therapeutic activity; it must of course be provided with a quartz window, since glass is opaque to wave-lengths of this order.

Description of Apparatus Examined

Three practical methods of measurement were compared against a standard kindly lent for the purpose by Mr. E. J. Bowen, F.R.S., of the Physical Chemistry Laboratory, University of Oxford. These were: (i) Weston double photovoltaic U.V.L. meter; (ii) Weston single photovoltaic cell U.V.L. meter; (iii) E.M.R.U. cadmium photo-emissive cell meter.

The standard apparatus used was a Jeffree spectrophotometer; this comprises a monochromator, a sodium cell, and an electrometer. Two drums calibrated in wave-length (range 2,200 A.U. to 6,000 A.U.) control the position and width of the monochromator slit, thus passing any desired line or band of wave-lengths within the stated range. A quartz-windowed sodium photo-emissive cell is connected in circuit with a quadrant electrometer and a suitable source of H.T. (about 160 volts); a variable resistance of 50,000 ohms permits adjustment of the electrometer to zero. The electrometer scale and needle are illuminated by an internal lamp and viewed through a microscope eyepiece. A switch is provided which short-circuits the input to the electrometer; the latter is adjusted to zero with the switch closed. To make a measurement the radiant source is placed at a suitable known distance from the receiving-plane of the instrument, the wave-length drums are adjusted to the desired band, and simultaneously a stop-watch is started. The watch is stopped when the electrometer needle has moved a convenient number of divisions. The electrometer is so calibrated that its scale-reading represents the number of gramme-molecular quanta of radiation per square centimetre received during the time period measured by the stop-watch; hence to compute gramme-molecular quanta per sq. cm. per second the scale-reading is divided by time in seconds. A simple calculation converts gramme-molecular quanta to microwatts.

(i) The Weston double-cell meter was lent by Messrs. Hanovia, Ltd., and is understood to be the standard used in their works laboratory. It comprises two photovoltaic cells and a microammeter; the cells are connected in opposition through a balancing control in such a manner that the potentials generated by them may be balanced until the meter reads zero. A switch provides two ranges of sensitivity. One cell is furnished with a fluorescent screen whose function is to convert ultra-violet radiation into visible light of longer wave-length, to which the cell is sensitive. A detachable clear-glass filter, transmitting visible light but cutting off the shorter ultra-violet wave-lengths, is also provided. In use, both cells are first screened by the glass filter, and the meter is adjusted to zero by means of the balancing control. Thus all radiation (visible and long U.V.) transmitted by the filter is effectively cancelled out. The filter is then removed; one cell, being unresponsive to U.V., will be unaffected, while fluorescence of the screen of the second cell will increase its output, deflecting the meter. A calibration chart is provided, which relates scale-reading with incident energy in microwatts per sq. cm.

(ii) The Weston single-cell meter was also lent by Messrs. Hanovia, and is the pattern carried by their service engineers for checking the efficiency of ultra-violet lamps at the user's premises. It comprises a single photovoltaic cell and microammeter; in appearance it resembles the well-known Weston photo-electric photographic exposure-meter. The cell is screened by a dark-purple filter, opaque to visible light, which presumably is backed by a fluorescent screen; it was not possible to investigate this in detail, since it would have entailed dismantling the instrument, which was not permissible in the circumstances of the loan. A calibration chart is provided which claims to relate scale-reading with minimum perceptible erythema time, while other charts indicate the scale-readings to be expected from various types of commercial ultra-violet-light sources when fully efficient.

(iii) The cadmium-cell apparatus was developed by the Electro-Medical Research Unit, Royal Air Force. It comprises an Osram quartz-windowed cadmium photo-emissive cell, type U.D.G. 7, having maximum spectral sensitivity in the 2,500–3,000 A.U. range; it is insensitive to visible and long ultra-violet radiation. This type of cell was selected on the recommendation of Mr. Bowen as most suitable for measuring the important therapeutic wave-lengths. Its output is fed to a single-stage direct-coupled amplifier, in whose output circuit an indicating milliammeter is bridge-connected; a balancing control is provided for zero adjustment. The whole is operated from A.C. supply mains via a self-contained power pack providing rectified, smoothed, and voltage-stabilized H.T.

Test Results

Throughout the following tests the supply voltage was maintained constant at 230 volts, A.C. 50 c/s.

Weston Double-cell Instrument.—This instrument was compared with the Jeffree standard. A quartz mercury-vapour arc tube was used as source, and comparative measurements were made, first with the bare source, then through filters isolating 3,340–2,895 A.U. and 2,650–2,537 A.U. (Bowen, 1942e). Throughout, the Jeffree standard was adjusted to cut off wave-lengths above 3,200 A.U. The agreement found, when both series of measurements were reduced to microwatts per sq. cm., was reasonably close; it was concluded that the absolute calibration of this instrument was satisfactory, and, of far greater importance, its response to radiation longer than 3,200 A.U. was small. Such a double-cell metre may therefore be regarded as providing an entirely satisfactory means of measuring the therapeutic content of the radiation from ultra-violet sources.

Weston Single-cell Instrument.—An initial test was made by Mr. Bowen at the Physical Chemistry Laboratory, Oxford. The instrument was placed in the full light of a quartz mercury-vapour arc tube, at such a distance as to produce a scale-reading of 50°. A clear glass plate, cutting off the shorter U.V. wave-lengths, was then interposed; the reading fell to 35°. Since the built-in dark-purple filter transmits little visible light, the residual reading of 35° must be chiefly due to the powerful but relatively inactive 3,650 A.U. line. It is known that short-wave production by a quartz mercury-vapour arc tube deteriorates more rapidly with use than long-wave production, hence a measurement which includes a large proportion of 3,650 A.U. radiation may give a misleading impression of the extent to which deterioration has occurred.

At Mr. Bowen's suggestion tests were carried out with a small series of new and deteriorated tubes; comparative measurements were made with the Jeffree and Weston instruments, the Jeffree instrument being adjusted to accept all radiation between 3,200 and 2,200 A.U. The deteriorated tubes were lent by Messrs. Hanovia, and were stated to show signs of 600–800 hours' use.

For simplicity in comparison, the indications of the Jeffree instrument were reduced to a "figure of merit" for each tube; the time required to produce a given deflection of the Jeffree electrometer is inversely proportional to the intensity of the incident flux, hence the reciprocal of the time is proportional to the intensity. The figure of merit shown in Table I was calculated on this basis, and was finally so adjusted (by multiplying by a constant) that a new arc tube chosen at random is rated at 10.5, corresponding to the indication of the Weston instrument.

TABLE I

	New Tube	Old Tubes			
		A	B	C	D
Jeffree	10·5	4·0	4·2	4·0	4·0
Weston	10·5	5·5	5·0	6·0	5·0
Discrepancy, % ..	—	+37	+19	+50	+25

These figures tend to confirm the view that the single-cell Weston instrument responds to wave-lengths over 3,200 A.U., since the meter indication falls off less rapidly than the 3,200–2,200 A.U. incident flux intensity. This is further borne out by the calibration figures provided with the instrument, which connect scale-reading with M.P.E. time; the inverse relation is non-linear, the M.P.E. time increasing more rapidly than the scale-reading diminishes. Allowance must therefore be made for this factor in interpreting the indications of the instrument.

E.M.R.U. Photometer.—A series of measurements similar to those described under (ii) above were carried out with the E.M.R.U. cadmium-cell photometer. The results are given in Table II; for ready comparison the Jeffree "figure of merit" has been adjusted to agree with the E.M.R.U. meter indication in the case of the new tube.

TABLE II

	New Tube	Old Tubes			
		A	B	C	D
Jeffree	12·5	4·8	5·0	4·8	4·8
E.M.R.U.	12·5	4·5	5·5	5·0	5·0
Discrepancy, % ..	—	−6	+10	+4	+4

It will be seen that the agreement is close, confirming the value of the cadmium cell for the measurement of the therapeutic band of ultra-violet wave-lengths.

Conclusions

The Weston double-cell photometer provides an entirely satisfactory means of measuring therapeutic ultra-violet light, and is extremely portable.

The Weston single-cell photometer has the advantage of lower cost, but responds to some extent to non-therapeutic wave-lengths.

The E.M.R.U. cadmium-cell instrument provides a satisfactory alternative to the Weston double-cell photometer where extreme portability is less important.

ANTI-M ISO-AGGLUTININS IN HUMAN SERUM

BY

MARJORY N. McFARLANE, M.D.

From the Departments of Pathology of the University of St. Andrews and Royal Infirmary, Dundee

The blood-group agglutinogens M and N were discovered in 1927 by Landsteiner and Levine, using rabbit immune sera. In contrast to the agglutinogens A and B, with their naturally occurring agglutinins α and β, no anti-M or anti-N antibodies are normally present in human sera. Further, the M and N agglutinogens are practically devoid of antigenic properties in man, and thus, as the transfusion of blood containing M or N does not give rise to iso-immunization against either factor, M and N can be disregarded in choosing blood for transfusion. To date only two instances of immune anti-M agglutinins have been recorded in human sera (Wiener and Forer, 1941; Wiener, 1942). In addition to these two examples Wiener (1943) cites five other instances of anti-M agglutinins in human sera, all of which are presumed to be of natural occurrence and not of immune origin. A single example of anti-N agglutinins in human serum was described by Singer (1943), but this case was not well substantiated.

In view of the rare occurrence of anti-M agglutinins—only seven out of hundreds of thousands of human sera tested by workers all over the world—it seems worth while putting on record the finding of another example. The serum in which this irregular agglutinin was found was detected during a serological examination of 60 patients who had suffered from a degree of toxaemia in pregnancy severe enough to require admission to hospital. For each patient the ABO blood group, MN type, and Rh factor were determined, and the serum was inactivated for half an hour at 55° C. and tested by titration against a panel of Group O cells of various M, N, and Rh types at 37° C., room temperature, and 4° C. A control of the patient's own cells was included.

The patient, Mrs. J. B., belonged to Group O Type N, Rh-negative (rr). When it was shown that her serum contained an irregular antibody she was asked to report back to hospital and bring as many members of her family as possible so that a further sample of blood could be obtained from her and the cells of her children and husband tested. Unfortunately the husband and first child were not available. The obstetric history and blood groups tested are as follows: (1) 1931, full-time, male, normal; (2) 1936, full-time, male, normal, Group O, MN, Rh-positive (R_1r); (3) 1938, premature, neonatal death; (4) 1940, full-time, female, normal, Group O, N, Rh-positive (R_1r). Mrs. J. B. has never received a blood transfusion.

Serological Examination

When freshly withdrawn the serum gave no reaction with any of the cells at 37° C. At 4° C. it agglutinated all the cells, including the patient's own, apparently from the action of a non-specific cold agglutinin. When the cell-serum mixtures were allowed to warm from 4° C. to room temperature it was noted that agglutination disappeared from the tubes containing the patient's own cells and those which lacked agglutinogen M, whereas all the cells containing M substance remained clumped. Accordingly the non-specific agglutinin was removed from the serum by absorption in the cold, leaving the whole blood overnight at 4° C. and next day separating the serum in the cold. Thereafter the serum gave specific reactions with cells containing agglutinogen M, irrespective of their Rh type, the results corresponding with those given by several anti-M rabbit immune sera. The titre of the treated serum against MM and MN cells was 1/16 at 4° C. and 1/4 at room temperature. It failed to react with the fourth child's cells, and in an extended investigation did not agglutinate any Rh-positive cells of type N—i.e., anti-Rh agglutinating antibodies were absent. These findings were confirmed by Dr. Race at the Galton Laboratory, Cambridge, to whom samples of blood were submitted.

Tests for incomplete or blocking anti-Rh antibodies were also entirely negative.

Comment

The finding of an irregular iso-agglutinin in the serum of an Rh-negative individual tempts one to consider that it may have originated through iso-immunization in pregnancy, since it is known that it could not have arisen as a result of blood transfusion. This possibility is strengthened by the occurrence of a neonatal death (third pregnancy), although there is no proof that this was due to haemolytic disease caused by the action of the irregular agglutinins (anti-M) in the maternal serum. In relation to this possible explanation it is noteworthy that the next child's cells do not contain agglutinogen M and are therefore compatible with the maternal serum; this would account for the absence of haemolytic disease in the fourth child even in the presence of maternal iso-immunization to agglutinogen M. It is difficult to suppose, however, that if iso-immunization to M substance had arisen in a Type N Rh-negative woman from a pregnancy in which the foetus carried both M and Rh factors there would not have been simultaneous production of anti-Rh. In Wiener and Forer's case (1941) of iso-immunization by transfusion the Rh-negative Type N individual developed both anti-Rh and anti-M agglutinins. The frequency of anti-Rh antibodies arising from pregnancy or transfusion as compared with the rarity of anti-M agglutinins indicates that the Rh factor is usually a better antigen in man than the M substance. Since the children and mother all belong to Group O the antigenic qualities of Rh have the optimum conditions in which to exercise their effect, for it is recognized that iso-immunization to the Rh factor is more frequent when the pregnancy is homospecific for ABO groups than when it is hetero-specific (Race, Taylor, Cappell, and McFarlane, 1943; Plaut, Barrow, and Abbott, 1945; Wiener, 1945). The fact that the fourth child, who is Rh-positive, did not suffer from haemolytic disease practically excludes maternal iso-immunization to the Rh factor as the cause of the loss of the third child, because once haemolytic disease has affected an Rh-positive child of an Rh-negative mother no subsequent Rh-positive child escapes haemolytic damage. If, therefore, iso-immunization to the Rh factor has failed to occur it is reasonably certain that the irregular anti-M agglutinin in this patient's serum is of natural rather than iso-immune origin.

Summary

A case is reported of anti-M agglutinins in the serum of an Rh-negative patient, and reasons are advanced for regarding it as of natural occurrence.

The work described in this paper was carried out under the supervision of Prof. D. F. Cappell, then Director of the East of Scotland Blood Transfusion Service, and I would like to thank him for his interest and criticism.

Medical Memoranda

Treatment of Chilblains by Paravertebral Sympathetic Block

In an article by Morris (1942) on the treatment of thrombophlebitis by paravertebral sympathetic block it was suggested that the condition is alleviated by the reduction of arterial and venous spasm, particularly the former.

Having a number of cases of severe chilblains which had resisted the usual forms of treatment, such as the administration of calcium orally and intramuscularly, I wondered whether a paravertebral block might not relieve and even cure the symptoms. On theoretical grounds it seems probable that in cases of defective circulation in the limbs the cold atmospheric conditions give rise to arterial and venous spasm. The spasm results in suboxygenation of the tissues, which of itself gives rise to further vascular spasm. This vicious circle is broken by the sympathetic block, and the circulation is restored to normal. Once having been restored it remains normal for a considerable period. Again on theoretical grounds, it would seem likely that the relief of the spasm by a short-acting local analgesic should not outlast the duration of analgesia, but in the following series this has not proved to be the case.

METHOD

The technique used is a slight modification of that summarized in M.R.C. War Memorandum No. 13 (1944). The analgesic employed has been amethocaine 1/1000 plus adrenaline, the effect of which lasts about two and a half hours. An hour before the injection the patient is given a hypodermic injection of morphine gr. 1/4 or 1/6. With the patient sitting, a 10-cm. needle is inserted four fingerbreadths from the midline at an angle of 40° to the sagittal plane at the level of the interval between the second and third lumbar spinous processes. It is pushed forwards and medially until it strikes the lateral aspect of the vertebral body. It is then withdrawn a little and re-inserted until it comes to rest in contact with the antero-lateral aspect of the vertebral body. It is pushed forward a further 1 cm. The stylet is withdrawn to make sure that the needle has not perforated a vessel. 20 c.cm. of the amethocaine–adrenaline solution is injected, and almost immediately there is a feeling of warmth in the ipsilateral lower limb. This feeling persists for the period during which the analgesic is effective. I have not yet attempted to use alcohol—first, because of fear of inaccurate placing of the solution; and, secondly, because it has not been necessary.

Of the eight cases treated six have proved to be cured throughout the whole of the winter months. The two most interesting cases were those of women, both of whom were deputizing for their husbands in butchers' shops as a war measure. After one injection these women were able to return to work in the shop with no discomfort, although cold and snowy weather persisted on and off for several weeks afterwards. Another patient was very neurotic and was unable to sit still while the injection was given. One woman recorded a certain degree of analgesia of both legs, obviously due to inaccurate placing of the solution; but it passed off after two hours, and a lasting relief of her chilblains followed.

The technique of the injection is not difficult to acquire after a little practice, and the results are so good for such a long period that it is well worth the time required to perfect it.

My experience suggests that there is a field for further investigation, not only in the treatment of chilblains but in other conditions where defective circulation appears to be due to vascular spasm.

Acute Haemolytic Anaemia due to Sulphonamide Administration

The following case illustrates well the acute and dangerous nature of this rare complication of sulphonamide administration—two-thirds of the patient's blood being destroyed by haemolysis in two days. The remarkably quick and complete recovery after cessation of sulphonamide administration and after blood transfusion is also typical.

CASE RECORD

On the evening of Sept. 11, 1944, a South African air mechanic aged 22 sustained minor second-degree burns of both legs from a petrol fire. He dressed himself with gentian violet and did not report sick until morning, when he was admitted to hospital. On admission his temperature was 100° F. His burns were cleaned with saline, dead skin was removed, and flavine in saline was applied. They were then lightly dusted with sulphanilamide powder and dressed with vaselined gauze. In view of his temperature he was put on a course of proseptasine (benzyl-sulphanilamide) by mouth also (1 g. 4-hourly). From then on, his clinical course was as follows:

Sept. 13.—Perfectly comfortable. Temperature normal.

Sept. 14.—Feeling rather miserable. Slight headache. Temperature 99.2° in evening.

Sept. 15.—Complained of feeling very weak, headache, and pains in both loins of a dull aching character. Complete loss of appetite. His burns were re-dressed in the morning as he complained of pain in the legs; they were perfectly clean. (Dressed with flavine—dusted with sulphanilamide powder—vaselined gauze.) Early in the afternoon he passed a quantity of urine which was deep red in colour and translucent. At the same time it was noticed that his conjunctivae were yellow. *Pathological reports* were:—(i) Urine: Alkaline; albumin +++; few leucocytes; few epithelial casts; bile, *nil*; alcoholic amidopyrine test, ++++. (ii) Blood (slide only): A marked poikilocytosis and anisocytosis, and polychromasia of the red cells; a few megaloblasts and normoblasts; no malaria parasites. Administration of proseptasine was stopped as soon as the haemoglobinuria was noticed. He had by then received a total of 17 g. in 3 days, plus a small amount of sulphanilamide locally on the burns (estimated at approximately 3–4 g.).

Sept. 16.—Temperature 100° F.; pulse 88. Felt very ill. Marked anorexia and nausea. Obvious icterus—lemon-yellow colour. Pains in loins + +, and tender on palpation over kidneys. Spleen and liver not palpable. Urine still a deep-red colour. Treatment: Fluids + + +; sod. bic. 30 gr. 4-hourly; burns were re-dressed to wash away all trace of local sulphanilamide; burns clean. Full Blood Examination:—R.B.C., 2,280,000 per c.mm.; W.B.C., 36,000 per c.mm.; Hb (Sahli), 55%; C.I., 1.2. Red cells: Anisocytosis, poikilocytosis, polychromasia of severe degree; megaloblasts and normoblasts in great numbers. White cells: polymorphs, 70%; monocytes, 10%; lymphocytes, 20%; no eosinophils or basophils seen. During the afternoon he was finding it difficult to drink enough fluid on account of nausea and occasional vomiting, so he was given 3 pints of fluid (glucose-water 2 pints, glucose-saline 1 pint) intravenously.

Sept. 17.—Symptoms exactly the same as on the 16th; felt very weak and looked very yellow. Urine: Alkaline; very deep red colour—translucent; few red cells; few leucocytes, no casts; alcoholic amidopyrine test, + + + +; albumin, + + + +. Blood: Hb, 32%; Group O (IV). In view of the haemoglobin level a transfusion was considered necessary. During the afternoon he was given two pints of Group IV blood by slow drip, followed by one pint of glucose-water. After the first half-pint of blood he suddenly felt much better and began to talk cheerfully.

Sept. 18.—Much better. Appetite returning. Still slight icterus of conjunctivae. No tenderness over kidneys—no pain in loins. Morning urine—light-red colour; afternoon urine—clear. Blood (afternoon): Hb, 37%; W.B.C., 13,900 (polymorphs 68%, lymphocytes 25%, monocytes 7%); R.B.C., 2,300,000 per c.mm. Red cells: Cells improved in appearance—poikilocytosis, etc., much less; very few normoblasts and megaloblasts seen (much fewer than in last film).

Sept. 19.—Felt well and cheerful, though still weak; appetite normal. Urine: Clear; alkaline; albumin, faint trace. Sugar, *nil*; no blood or casts; few leucocytes only.

A final blood examination, made on Sept. 22, was as follows: R.B.C., 2,910,000; Hb, 58%; C.I., 1.0; W.B.C., 23,000 (polymorphs 74.5%, lymphocytes 20%, monocytes 5%, eosinophils 0.5%); no megaloblasts, normoblasts, or myelocytes seen. Fragility: normal—haemolysis in 0.3% saline.

His further clinical course was uncomplicated, and he was discharged back to duty five days later.

This man had never previously been ill, and was quite certain that he had never been given sulphonamide drugs before. It is regretted that no further investigation could be made, as the case occurred in a mobile field hospital of the R.A.F. on active service.

Duodenal Atresia in a Newborn Infant

Successful treatment of this condition is, I believe, uncommon; the following case may therefore prove of interest.

Case History

The baby, a male, was born on May 26, 1945, in the Royal Maternity Hospital, Belfast. The weight at birth was 8 lb. 2 oz. There were two previous children, both normal and healthy. On the first day he vomited fluid which was viscid and stained with bile. The vomit was projectile in character and was more severe on the following day. Meconium was passed on the third and fourth days, and as the vomiting was still more pronounced a barium-meal examination was made. This showed almost complete gastric retention at four hours.

The baby was transferred to the Belfast Hospital for Sick Children, its weight having fallen to 6 lb. 4 oz. There was some distension of the upper abdomen, and increased gastric resonance was noted on percussion. The general condition was fairly good, although dehydration was obvious. It was decided to attempt gastro-enterostomy, and dehydration was combated by subcutaneous infusion. Laparotomy was performed (Mr. J. S. Loughridge), when it was found that the stomach and first part of the duodenum were much dilated. There was a good deal of matting of the small intestine by adhesions. The caecum was freely mobile and was situated in the mid-abdomen. A side-to-side gastro-enterostomy was done between the stomach and jejunum. The operation time was 35 minutes.

Apart from considerable shock after operation, progress was uninterrupted. Thirst was relieved by half-normal saline by mouth, and next day breast milk was given by means of a Belcroy feeder. On the fourth day success was assured, and a gain in weight of 10 oz. was recorded. The baby was discharged home on the seventh day after operation. Progress has been uninterrupted, a steady gain in weight being reported.

I wish to express my thanks to Dr. F. M. B. Allen and Mr. J. S. Loughridge, under whose care the infant was, for permission to publish these notes.

Reviews

SURGERY OF THE HAND

Surgery of the Hand. By Sterling Bunnell, M.D. (Pp. 734; illustrated. 72s.) London: J. B. Lippincott Company.

Dr. Bunnell's remarkable book is the outcome of a life devoted to one special field of surgery, and it is a brilliant achievement. Most people accept their hands without any thought of the amazing complexity of their mechanism or of what a deformity or an injury may mean. To most surgeons this book will be a revelation.

The author has attacked his subject with massive thoroughness. Starting with the study of comparative anatomy, he then discusses the normal mechanism of the hand and methods of examination in great detail, and these chapters are ingeniously followed by a chapter on the reconstruction of the hand to restore its normal mechanism. The correction of deformities, whether due to contractures of the soft structure or to abnormalities of the bones, is then discussed. There follows a chapter on the repair of injured nerves, evidently the result of wide experience, and the author then takes up the even more difficult problem of the repair of tendons and of the intrinsic muscles of the hand. A large section follows devoted to the mechanism of injuries and to infections of the hand and their modern treatment, and the volume ends with a discussion on congenital deformities and of neoplasms.

So far as we are aware no book has ever been produced dealing with such thoroughness with injuries of the hand, and certainly none which so impresses upon one the vast importance of this subject. The author seems to deal with nerve injuries, deformities, and infections with equal facility, and perhaps the chief attraction of the book is that it so obviously all arises from his own experience. It is impossible to give any idea of the vast amount of detail which he has brought together, or of the minuteness with which the most complex procedures are described, but so thorough are the descriptions that any competent surgeon will be able to carry out in his own practice every operation. The illustrations throughout are superb, whether they are photographs or diagrams to explain minute points of detail. We would congratulate the author on a magnificent achievement, and urge any surgeon who ever has to operate on a hand to make his own the vast experience recorded in this volume.

MICROBIAL ANTAGONISMS

Microbial Antagonisms and Antibiotic Substances. By Selman A. Waksman. (Pp. 350; illustrated. $3.75.) New York: The Commonwealth Fund. 1945.

To see penicillin in correct perspective it is necessary to understand that it is only one, though therapeutically the most useful, of many similar substances formed by micro-organisms. That antagonism between different species is expressed in the formation of such substances has been recognized since the earlier days of Pasteur's work. For a broad conspectus of this phenomenon, long neglected in its wider aspects, and now exciting the liveliest interest, we can recommend Selman A. Waksman's new book, *Microbial Antagonisms and Antibiotic Substances.* The author is microbiologist to the New Jersey Agricultural Experimental Station; he has done important work in identifying antibacterial substances produced by *Actinomycetes,* and is largely responsible for popularizing the use of the word "antibiotic." He almost reconciles one to its use by contrasting "antibiosis" with symbiosis, these being two opposite forms of mutual relationship which mixtures of microbic species may exhibit in Nature. The subject is approached by way of the flora of soils and water and the competitive or antagonistic interrelationships which exist between the species found there. Methods of isolating and testing antibiotic substances are then described, following which there are accounts of those produced by bacteria, *Actinomycetes,* and fungi; the numbers of these hitherto identified are given as 11, 7, and 15 respectively, but it need scarcely be said that besides these adequately studied and characterized products there are believed to be many others. Other chapters deal with the chemical nature of these products, their mode of action, and their practical application for the control of disease in both animals and plants. There is an extensive bibliography (1,016 references given in full) and two indexes are provided, one being confined to the names of micro-organisms.

This survey, apart from its value as a scholarly treatise on a subject of great importance, seems almost to introduce a new philosophy into microbiology. Viewed as a series of warring tribes, our microbic friends and enemies seem more human—if such an expression may be used—and a good deal more vulnerable, than we had thought.

TELEPATHY AND THE GROUP MIND

Telepathy. An Outline of its Facts, Theory, and Implications. By Whately Carington. Second edition. (Pp. 176. 12s. 6d.) London: Methuen and Co. 1945.

Largely as a result of very careful experiments by such workers as Dr. Rhine and Dr. Soal, telepathy, clairvoyance, and precognition have been shown to be fit subjects for scientific research. In the words of Dr. Thouless, "the evidence for the reality of the phenomenon is now so overwhelming that scepticism can only be justified by ignorance of the experimental results." It is not so much that the sceptical feel called on to boggle at the results as that they find them impossible to fit into any reasonable theory. It is greatly to the credit of Mr. Carington, who has himself done some notable experiments, that he has evolved a theory which, though incompatible with a purely materialist philosophy, is a truly scientific one in that it can itself be tested by experiment.

Most of the worth-while experiments have been of the card-guessing type, in which high proportions of successes have been obtained despite extreme precautions to prevent any normal communication between experimenter and subject. Possible explanations by a "sixth sense" or by "wireless waves" can apparently be excluded. It makes no difference to success whether experimenter and subject are separated by the wall of a room or by a range of mountains. Mr. Carington suggests that we should not look for explanation along such lines at all. He proposes the theory that the sensa and images which are our minds are to some extent independent of physical processes in the brain, and are not wholly independent of the sensa and images which are the minds of other people. So that if A and B are presented together to the mind of Smith, not only will A be subsequently likely to call up by a process of association the image of B when it is presented to Smith, but also when it is presented to Brown. Similarly, when the experimenter in a card-guessing experiment turns up a certain card this card is associated in his mind with the idea of the experimental situation, and the subject, who is placed in the same situation, has a more than chance probability of associating with it the image of the same card. The laws of association may then be expected to obtain; and in fact there is some evidence that the laws of recency and repetition do hold good.

This leads Mr. Carington to a discussion of the group mind. He points out that minds which hold a great deal of their sensa and images in common may be especially favourably constituted for telepathic communication. One could suggest, for instance, testing this by having husbands and wives, or, better, uniovular twins, as experimenter and subject. Groups of people who lead very similar lives, such as primitive tribes, would be expected to be more liable to telepathy than civilized groups; and in the case of some animals, such as shoals of fish or armies of ants, it would not be surprising if the evidence for a group mind were still stronger.

This is an extremely interesting and, though often highly speculative, a thought-provoking book.

OTO-RHINO-LARYNGOLOGY

Diseases of the Nose, Throat and Ear. A Handbook for Students and Practitioners. By I. Simson Hall, M.B., Ch.B., F.R.C.P., F.R.C.S.Ed. Third edition. (Pp. 459; illustrated. 15s., plus 9d. postage.) Edinburgh: E. and S. Livingstone. 1944.

A third edition of this book is evidence of its popularity with those students who require a general though necessarily superficial survey. Dr. Simson Hall states that the subject-matter has been thoroughly revised and brought up to date, but it is not easy to find confirmation of this. Chemotherapy is relegated to an appendix instead of being incorporated in the text at the appropriate places; nor is a proper appreciation of either its status or its limitations attempted; and the magic word "penicillin" does not appear at all. By no means all the errors of the previous editions have been eliminated. For instance, the manipulation described for the introduction of the Eustachian catheter could not possibly induce it to enter the orifice of the tube, and the strengths of cocaine in solution recommended are much greater than necessary and not without hazard. At present the indications for the fenestration operation for otosclerosis and other forms of deafness are certainly unsettled, but are the cause of much interrogation both of practitioners and of otologists; yet the author gives no guidance, though he is admittedly one of the few in Great Britain entitled to speak with authority on the subject. Useful as the book surely is, the author has still not made full use of the opportunity for instruction which such a textbook provides.

Notes on Books

Mr. Aleck Bourne's *Synopsis of Obstetrics and Gynaecology* has now reached its ninth edition (Bristol: John Wright and Sons; 21s.). There have been many changes, both of addition and of omission. This book is, as before, an attempt to present facts to the student in a precise manner and thereby give him a foundation for building up his own experience. As the author says in his preface, "During our younger years we must learn facts. . . . No book, least of all a synoptic book, can replace attendance in the clinics."

Dr. J. G. Baumgartner's book *Canned Foods: An Introduction to their Microbiology* was highly commended in these columns on Aug. 7, 1943. A second edition is now published by J. and A. Churchill Ltd. at 12s. 6d. Among various changes from the original text there is a new chapter summarizing some of the literature on the microbial condition of marketable tinned food and indicating briefly the practical aspects of this matter. A number of methods useful in the bacteriological control of such foods have been added, and these, together with raw-material tests, form the subject of another chapter. In its present expanded form the book will prove even more helpful to medical officers of health and sanitary inspectors, and to public health and industrial bacteriologists.

A ninth edition of J. M. Lowson's well-known *Textbook of Botany*, revised and largely rewritten by Dr. W. O. Howarth and Dr. L. G. G. Warne, of the Department of Botany in the University of Manchester, has been published at 12s. 6d. by the University Tutorial Press, Ltd., Clifton House, Euston Road, N.W.1. The text has been brought up to date to conform with modern ideas, modern teaching methods, and examination requirements, and many illustrations have been drawn for this edition by Miss M. W. M. Jepson, a skilled botanical artist.

John Wright and Sons Ltd. have published at 5s. a 23rd edition of *Our Baby: for Mothers and Nurses*, by the late Mrs. J. Langton Hewer. The booklet (now in its 223rd thousand) has once again been revised from the medical point of view by Dr. Margaret Scott-Brown, with the aim of leaving Mrs. Hewer's fundamental doctrine unchanged while bringing the material into line with modern ideas.

Rebuilding Family Life in the Post-War World, edited by Sir James Marchant, with an introduction by Lord Horder, was noticed in a leading article on Aug. 25 (p. 258). In addition to the 2s. paper-bound edition a 3s. 6d. edition is now available in cloth boards. The publishers are Odhams Press, Ltd.

We have received from the Sterling Hall of Medicine, New Haven, Connecticut, the fifth annual report of the Historical Library of Yale University School of Medicine. This includes a review of the first five years by Dr. J. F. Fulton, chairman of the Advisory Board. Six years have elapsed since Harvey Cushing's death, and in that interval there has been ample opportunity to see the wisdom of his plan for combining his books with those of his friends in the hope of building up at Yale a library on the history of medicine and science that would be second to none.

In view of the acute shortage of nurses, the Minister of Health has been in consultation with the Minister of Labour and National Service and the Service Ministers with regard to arrangements for the early release from H.M. Forces of individual State-registered nurses on account of their special qualifications or to fill key positions in the civilian health services. It has been agreed that where the Ministers of Health and of Labour are satisfied on the application of an employing authority that the early release of a particular nurse is desirable, on the ground that he or she is needed either for a key position or for a vacancy requiring the possession of a special qualification which cannot otherwise be filled, the Service Ministers will consider release under Class B, assuming that the nurse is willing to accept such release.

CARBON MONOXIDE POISONING

The danger of carbon monoxide has existed since fire was known to man. It is a colourless and odourless gas which arises from the incomplete combustion of carbonaceous matter. The introduction of coal-gas for domestic use and the invention of the internal combustion engine in the last century have heightened the risks. At present carbon monoxide is a popular suicidal poison, besides being a serious industrial hazard; it is, in fact, the cause of between one-half and one-third of all the reportable gassing accidents in factories in Great Britain: 226 cases were reported in 1941, with 239 in 1942 and 225 in 1943.[1] The risk exists in many industries, but blast furnaces and gas-producers account for nearly a quarter of the cases. In the chemical industry the manufacture of ammonia by the Haber and Bosch procedure, the synthetic production of methane and methanol, and the manufacture of soda with the Le Blanc process are the principal hazards, though charcoal burners and carbide workers may be exposed to risk. In the mining industry the main hazards result from fire-damp explosions, but the gases of explosives sometimes contain high concentrations of CO, so that blasters may be heavily exposed. Workers in the clothing, ceramic, and electrical industries, besides linotype operators, chimney sweeps, firemen, boiler-cleaners, cooks, and bakers, may become exposed, as well as workers in the motor industry—for instance, in garages and repair shops.

A full review of the literature of the hazards of carbon monoxide and of the mechanism of its action has now been published by von Oetlingen.[2] The gas possesses the property of combining with the haemoglobin of the red blood cells to cause chemical asphyxiation. The amount of carboxyhaemoglobin formed depends on the concentration in the atmosphere, the duration of exposure, and the respiratory rate of the person exposed. An increase in the temperature, humidity, and carbon dioxide content of the air, or a decrease in the oxygen content, however, will stimulate respiration and hence the amount of CO absorbed will be increased. The formation of carboxyhaemoglobin causes a corresponding reduction in oxyhaemoglobin, but the toxic effects are not entirely due to the anoxaemia brought about by this reduction in the oxygen-carrying power of the blood. The oxygen supply to the tissues is further reduced, because carboxyhaemoglobin interferes with the dissociation of oxyhaemoglobin, besides causing a reduction in the available reduced haemoglobin and in this way interfering with the carrying and dissociation of CO_2. Carbon monoxide may also react with other haem-containing pigments such as pseudo-haemoglobin, myoglobin, or cytochrome, but it is not certain whether the function of these pigments, or of those found in the brain, is affected by the poison. The early symptoms of poisoning include giddiness, a sense of oppression in the chest, a band-like feeling of constriction round the head, nausea, and throbbing of the heart; then follows loss of power in the lower limbs, and the patient falls helpless and loses consciousness. With concentrations of carboxyhaemoglobin below 20% the symptoms are negligible. They increase between 20 and 50%, while with concentrations between 50 and 80% there is danger to life from respiratory paralysis and cardiac failure.

Polycythaemia not infrequently results from CO poisoning, but this phenomenon is not merely an attempt of the organism at compensation. Hartridge[3] pointed out the slow return to normal values and argued against a temporary hyperactivity of the blood-forming organs, while Brieger[4] produced in a dog permanent polycythaemia which persisted more than a year with red blood cells 40% above the original level and haemoglobin 30% above it. Barcroft[5] has shown that the increase in circulating blood cells may be due to a contracture of the spleen, and Dittmar,[6] among others, has suggested that the phenomenon is due to a central mechanism possibly resulting from injury to the corpus striatum. Polycythaemia, therefore, should be considered as an alarm signal. Analysis of the clinical picture and of the pathological findings in CO poisoning, especially in the circulatory and central nervous systems, appears to indicate that the sequelae are more serious than would be expected from mere anoxaemia of similar degree. These include headache, chest symptoms, coldness of the extremities, psychoses which are mostly of a depressive kind, prostration, and loss of vitality; while more remote effects are paralysis, loss of memory, hallucinations, and dementia.

The treatment of carbon monoxide gassing must be directed to the restoration of normal breathing and the abatement of shock. The patient must be removed immediately from the contaminated atmosphere and artificial respiration started; the essential need is for oxygen to overcome the decreased oxygen-carrying power of the blood and to promote the dissociation of carboxyhaemoglobin. Cold and physical exertion should be avoided. Venesection, lumbar puncture, catharsis, and intravenous injections of hypertonic solutions may be considered when hyperaemia and oedema of the brain appear. Morphine and atropine must never be used. The former is a depressant of the respiratory centre, while the latter causes dilatation of the bronchioles, interfering with the elimination of CO through the lungs. As with all industrial accidents, however, prevention is much more important than treatment, and this can be achieved by insisting on proper lay-out and maintenance of plant and adequate safety precautions—such as the erection of warning notices, and the provision of safety belts and breathing apparatus. Service respirators are not proof against CO, but special breathing apparatus has been manufactured consisting of the usual type of Service face-piece connected to a length of strong wire-embedded air-piping, the free end of which is secured in the fresh air. There are several methods for detecting and estimating CO in the atmosphere. The oldest makes use of mice or canaries, which resemble human beings in their response to it. Taken into a confined space in a cage and kept under observation by the workers, they will show signs of distress if dangerous fumes are present and the place needs to be evacuated. Several proprietary instruments are also available; they make use of the reaction with either palladium chloride or iodine pentoxide, and though convenient do not indicate concentrations of less than about 50 parts in 100,000 of air.

Is there such a thing as chronic carbon monoxide poisoning? It depends how one interprets the word "chronic." Chronic poisoning usually means the repeated or continued administration of small quantities of a poison resulting finally in toxic symptoms. Manifestly, however, there are circumstances in which "repeated mild acute" poisoning and "chronic" poisoning amount almost to the same thing. There is no evidence that CO as such, or in combination with other compounds, remains in the tissues for any considerable period of time, and so far there is no evidence that concentrations of CO which cause no acute subjective or objective symptoms will affect any structures of the organism in such a way as to lead to functional or permanent injury. The methods available for measuring small amounts of carboxyhaemoglobin have not so far been very sensitive, but it is hoped that with the development of new and accurate spectrophotometric methods it will be possible to establish how long CO absorbed by a man during an eight-hour work-shift remains in the tissues. On the whole, the reported clinical signs and symptoms of "chronic" carbon monoxide poisoning are indefinite and not characteristic; headache, vertigo, weakness and ataxia of the legs, and psychic manifestations are those most often mentioned. Lewey and Drabkin[7] have reported some experiments in which dogs were exposed for 5½ hours a day, 6 days a week, for 11 weeks, to an atmosphere containing 0.01 vol. % of carbon monoxide, which caused a carboxyhaemoglobin level of 20%. This concentration was chosen because the U.S. Department of Labour, following a report by Bowditch and his colleagues,[8] had set 0.01 vol. % as the limit of safe concentration of CO in the air in industrial plants. All the dogs showed consistent disturbances of postural and position reflexes and of gait, and some an abnormal electrocardiogram[9] characteristic of anoxia. Histological examination of the central nervous systems three months after the end of the experiment showed changes in the cortex and white matter of the cerebral hemispheres, in the globus pallidus, and particularly in the basal ganglia. They followed in their distribution the course of the blood vessels, the walls of which were damaged only occasionally. The implications of these findings with respect to chronic CO poisoning in man are uncertain, but it is clear that repeated prolonged exposure to 0.01 vol. % of carbon monoxide is not innocuous for the heart and central nervous system in dogs. There is need, therefore, for work to clarify the situation in man, and to establish whether chronic CO poisoning does or does not exist.

SURGICAL SCIENCE IN ENGLAND

The Scientific Report of the Royal College of Surgeons of England for the year ending July 31, 1945, not only is a record of the work in the scientific departments but contains many indications of the future policy of the College in regard to these departments. Perhaps the most important new development has been the inauguration of lecture courses in anatomy, applied physiology, and pathology, to which is being added a course of lectures on surgical topics by prominent surgeons. The College appears to have taken the first step towards becoming a postgraduate teaching institution. Whether it will go further and link up its teaching in the medical sciences with a university remains to be seen. The Goodenough report suggests that institutes for postgraduate education should be either departments or schools of universities. The advantages to be derived from a close liaison between the College and the University of London are too many to be lightly dismissed.

With the appointment of Prof. Wood Jones to the Collins chair of anatomy the three departments of anatomy, pathology, and experimental surgery have each a head. The report suggests that in anatomy and pathology the primary duty of the heads of these departments is to rebuild the museum collection. It is to be hoped that sufficient staff will be given to these departments to ensure that the time of the heads of them will not be occupied exclusively by museum work. These departments can do much to advance knowledge and to disseminate it. The College Museum is the obvious place to become the repository of a national type collection of tumours. The experience in this field of its professor of pathology would make such a collection unique within a very few years. It is most encouraging to note the great number of accessions to the museum collections of anatomy and pathology. When it is remembered how many young surgeons, always strong supporters of the College Museum, are still on national service, the year's total of new specimens is a good augury for the future.

The brief summary of the work in the research laboratories during the war years emphasizes the importance of patient work on some fundamental theme out of which develop inevitably lines of attack on diverse problems. Starting with the observation that infusions of plasma after the cessation of haemorrhage caused blood dilution to reach an upper limit after which further dilution was not observed in spite of continued plasma infusion, this led to experimental work which showed that the plasma proteins infused are not retained in the blood stream but move out of it at a relatively rapid rate once the normal blood volume has been attained. In a series of experiments the mobility of some of the body proteins was demonstrated and the ability of these to move into the blood stream under suitable conditions was proved. The steps which led to a study of protein synthesis in the liver in healthy animals and in patients suffering from one or other of the various hepatic diseases are set out in detail in the report. The great increase in protein destruction consequent on any trauma has been noted by many observers. Destruction also occurs in hepatic diseases such as acute infective hepatitis. The work on hepatic disease by the laboratory staff has provided many valuable clues to the causes of nitrogen loss after injury, and it is to be hoped that these will be followed up. Nothing is more disheartening to a patient than a slow convalescence. War experience, in which the College laboratories shared, has demonstrated how recovery can be speeded up and healing accelerated when the feeding of patients after injury or operation is tackled on scientific lines. The few observations recorded in the report which were made in Holland by the laboratory staff after the liberation of that country whet the appetite for the full report of this work. Cessation of the healing process under conditions of acute protein deprivation is an interesting observation and raises many problems worthy of study. The report of the laboratories ends most appropriately by posing several questions on the problem of protein breakdown after trauma: "Is the breakdown an essential process in the initiation of repair, or is it merely the effect of trauma? The breakdown process when brought to a halt or slowed down because of extreme emaciation is coincident with a cessation of healing. If we regard the processes of repair as being but a special case of growth it is possible that the hormones essential for growth of the immature animal are equally essential in repair."

OCULAR SIGNS OF ARIBOFLAVINOSIS

Much confusion still exists concerning the ocular signs of ariboflavinosis, or riboflavin deficiency. After the publication in 1940 of the observations of Sydenstricker and his colleagues[1] on the ocular manifestations of this condition, circumcorneal injection and corneal vascularization were accepted as certain diagnostic signs and used in nutrition surveys as an index of riboflavin nutrition. On the basis of ocular signs the incidence of ariboflavinosis has been reported as high as 99.5%[2] and as low as 3%[3] in the subjects examined. The incidence reported seems to depend on whether the observers were ophthalmologists—and therefore conversant with the appearance of the limbus under different conditions and with the different kinds of corneal vascularization—or not. The ophthalmologists report a low incidence of ariboflavinosis based on ocular signs. Bessey and Wolbach[4] in 1939 showed that the earliest detectable sign of ariboflavinosis in rats is corneal vascularization. Since then some observers have extended this to include circumcorneal injection, or engorgement of the limbic loops. Others have not discriminated between this and ciliary congestion, and between an engorged limbus and an actual invasion of the cornea by new vessels.

Is circumcorneal injection pathognomonic of riboflavin deficiency? Stannus[5] has examined between four thousand and five thousand eyes by slit-lamp microscopy, and has seen both corneal vascularization and circumcorneal injection without any evidence of ariboflavinosis. The vessels of the limbic plexus may appear avascular because they are constricted and empty. The slightest stimulus may cause them to become congested and engorged. This occurs in all varieties of conjunctivitis, in those whose eyes are exposed to heat and dust, cold wind, bright light, and mild infection. It may also result by just rubbing the eye,[6] and may come and go in the same individual with considerable rapidity. Engorgement of the limbic vessels is, therefore, not a sure sign of ariboflavinosis, which should be diagnosed only when new capillaries are observed budding from the apices of the limbal loops and extending on to the cornea. Even then the change should be present in both eyes and round the whole corneal circumference, and it should respond rapidly to treatment with riboflavin. Corneal vascularization may also occur in the absence of ariboflavinosis. Thus it has been noted as a result of vitamin-A deficiency, tryptophane deficiency, injury to the corneal epithelium by chemical irritants, and diseases such as trachoma, phlyctenular keratitis, and any superficial keratitis. The instillation of soap solution into the conjunctival sac may also cause collapsed, afunctional blood vessels in the cornea to become engorged.

Ida Mann[7] has recently recorded a new type of corneal lesion due to riboflavin deficiency. The cornea shows marginal vascularization and opacities in the substantia propria. The vascularization, which is distinctive and differs from that hitherto described, is in the form of parallel, radially arranged loops springing from the apices of the loops of the limbic plexus and extending over the cornea in three arcades beyond this, slightly more than half-way to the pupil margin. The vessels, which are so engorged that they stand out from the surface, are mostly subepithelial, although in the region of the opacities they penetrate the substantia propria. They extend all round the circumference of the cornea. This is probably a true manifestation of ariboflavinosis, as the engorged vessels rapidly empty and the opacities clear after treatment with riboflavin.

RECURRENT PAROXYSMAL ABDOMINAL PAIN

Transient acute abdominal pain affecting an apparently healthy person is often difficult to explain; if the symptoms are of short duration, and if operation is clearly contraindicated, precise diagnosis may be impossible. From time to time, however, little groups of cases are separated from the mysterious majority, and the number of the unexplained grows gradually less. Attacks of abdominal pain have long been known in subjects of erythema and of purpura; fifty years ago Osler[8] wrote of the visceral complications of the "erythema group," and the acute abdominal manifestations of Henoch's purpura have been recognized for even longer. Siegal[9] has now attempted to distinguish in a separate clinical category an acute affection similar to the abdominal accompaniments of erythema and purpura but free from florid cutaneous eruption. According to Siegal this syndrome is characterized by recurrent paroxysms of severe abdominal pain, diffuse and cramp-like or localized and gnawing. The attacks are said to begin as a rule in the second or third decade, and they continue for many years without affecting the patient's general health. Early attacks may be noted only once or twice a year, but later a more frequent cycle is established, the pain recurring weekly or monthly. The temperature rises during an attack, sometimes to 104° or 105° F. Nausea, vomiting, and diarrhoea may occur; the abdomen is tender, the abdominal muscles may be spasmodically contracted, and rebound tenderness is sometimes elicited. There may be pain in the chest, too, and sometimes shoulder pain; prostration may be extreme, and the white count is high.

One of Siegal's patients was submitted to laparotomy during an acute attack of pain, and the subserous vessels of the ileum, caecum, and sigmoid colon were seen to be congested. From this evidence, and from the abdominal tenderness and rebound tenderness which are present during acute attacks, Siegal suggests that the name "benign paroxysmal peritonitis" be applied to the condition until the aetiology and pathogenesis are better understood. There is still room for argument whether the existence of this syndrome as a distinct entity is justified, and whether, if it is justified, Siegal's title for it is suitable. But Siegal goes further, and suggests, though only tentatively, that the abdominal symptoms are due to allergy. A family history of allergy was elicited in the majority of cases, and urticarial wheals were occasionally observed during acute attacks, but positive allergic reactions were seldom elicited in affected individuals. In no case was any allergen proved capable of initiating an attack, and the hypodermic administration of adrenaline gave no relief from pain. That acute abdominal symptoms may accompany urticaria and angioneurotic oedema is certain, and there is no reason to doubt that some forms at least of paroxysmal abdominal pain may be allergic in origin, even if unaccompanied by cutaneous manifestations. It would be wrong, however, in any individual case to ascribe acute abdominal symptoms to hypersensitization unless clear evidence of allergy were obtained. The only certain proof would be the precipitation of an attack of pain by the administration of the responsible allergen. If Henoch's purpura be excepted no precise account yet exists of an abdominal syndrome which, from the abdominal evidence alone, can be regarded as characteristic of, and peculiar to, the allergic state; it is equally doubtful whether the abdominal symptoms of frankly expressed allergy are due to peritonitis.

HUMAN LISTERELLOSIS

Listerella or *Listeria monocytogenes,* so called because of the blood picture associated with it, was first identified by Murray, Webb, and Swann as the cause of an epizootic among laboratory rabbits at Cambridge. Since then infection by this organism has been recognized in various other animals, and 23 cases of human infection have been reported. These are reviewed by M. M. Kaplan,[1] together with 13 earlier cases almost certainly of the same nature, although the organism in the then state of knowledge was merely described as a diphtheroid bacillus. All 36 patients suffered from one of two conditions—a meningitis with a high mortality, or infectious mononucleosis. The most recent case of the latter type was fully described by Webb[2] himself. The patient was a medical student with typical infectious mononucleosis, including a heterophile agglutinin titre of 1 in 2,048. The organism was cultivated from the blood, and shown by exhaustive examination to be a true *List. monocytogenes*; the only element of doubt in these findings was the absence of the agglutinin for the organism itself in the patient's blood after recovery. It is by no means accepted that *List. monocytogenes* is even a common cause of infectious mononucleosis; the few reported cases in which it has been found suggest only that further search for it should be undertaken. As Kaplan points out, there are other mysteries connected with this organism: neither its natural habitat nor the portal of entry is known, and it is a striking fact that no carrier has ever been identified, either human or animal. Infection in newborn infants nevertheless suggests transmissibility from an unrecognized human source. Both the experimental and the human disease respond to sulphonamides, but the organism is insensitive to penicillin. Only a condition which may be described as "Listerella consciousness" among clinical bacteriologists will enable knowledge of this interesting infection to be extended. Whenever pathogenic activity is attributable to a short thin Gram-positive bacillus exhibiting motility, it may be worth while to inoculate a rabbit intravenously: a sublethal dose produces an extreme mononucleosis, and the main result of fatal infection is the production of focal necrosis, most marked in the liver but also found in the spleen and lungs.

EFFICIENCY OF ULTRA-VIOLET APPARATUS

In another column will be found a paper by Fl. Lieut. B. C. Elliott on the efficiency of ultra-violet-light apparatus which may, at first sight, appear too technical for the majority of the medical profession. The paper has, however, aspects of clinical importance, and the conclusions reached, based as they are on well-proved scientific facts and careful experiments, should be known to every practitioner who employs ultra-violet light either himself or by prescription. Reduced to simplest medical terms Elliott's paper poses three questions: (1) Do ultra-violet lamps deteriorate with use to any important degree in the output of therapeutic biological rays? (2) Is the apparatus used for testing during manufacture efficient as a means of ensuring that the necessary biological rays are present in apparatus sold to the public? (3) Is the testing apparatus commonly used for servicing an efficient means of measuring those biological rays? The author answers the first two questions in the affirmative and the third in the negative. It will be well, therefore, to examine these questions and answers from the clinical point of view. An ultra-violet lamp which deteriorates in the most potent of its therapeutic rays more rapidly than in other parts of the spectrum can, clearly, lead to false clinical impressions of its efficiency as a therapeutic agent. Elliott's researches were directed to the production of a simple portable testing outfit, the sensitivity of which was maximum for the more therapeutically valuable rays. During the course of his investigations the laboratory testing apparatus of one of the largest manufacturers was submitted for investigation and found to be fully efficient. This by itself is a comforting thought, and means that care and scientific precision are exercised before new models are sold to individuals or the trade. But when he came to look into the servicing side and the efficiency of second-hand models he found a completely different state of affairs. The apparatus provided for use during servicing is of a type that can give a misleading picture of deterioration in the biologically active part of the spectrum. The author has not found it possible to comment on the apparatus of other manufacturers than the one who holds a virtual monopoly in ultra-violet lamps for therapeutic purposes. For example, the type commonly known as the cold quartz ultra-violet lamp does emit the biologically active rays, but its usual output in comparison with the new electronic mercury vapour tubes is relatively poor. He has designed, with the help of Mr. E. J. Bowen, F.R.S., of the Nuffield Physical Chemistry Laboratory, Oxford, an easily operated, robust, portable testing apparatus, which takes into consideration all the necessary medical desiderata, and it has been checked over a long period against high-precision apparatus.

The lessons to be learned from Elliott's paper are therefore that all therapeutic ultra-violet lamps should be serviced at regular intervals and that the testing should be carried out only with apparatus approved by an impartial body such as the National Physical Laboratory. It behoves us, therefore, to ensure that deterioration of such apparatus is not mistaken for clinical inefficiency.

LESSONS OF WARTIME EXPERIENCE

[From a Correspondent]

Those of us who have served as medical officers in tropical theatres of war may at times have envied our brethren in Europe the superior facilities for work which they enjoyed. But to the physician at least medicine in the Tropics offers interest, variety, and an insight into the large-scale problems which can hardly be obtained elsewhere. It is a mistake to think of tropical medicine as being exclusively concerned with "tropical" diseases. These there are in plenty, but as well as, not instead of, the more familiar illnesses of temperate climates. There is danger, now that the war has ended so abruptly, lest we shut the door on the experiences of the past, forgetting alike failures and successes in a pleasant glow of self-congratulation. It will be a pity if we do not try to profit by what we have learned, for the problems are far from solved.

The lesson which was perhaps most firmly driven home was the real meaning of hygiene and sanitation. The British Armies operating in the Middle East, Africa, India, and S.E.A.C. were for the most part surrounded by populations at a very low standard of Western culture. In all these theatres some, and in many of them the greater part, of the troops for which British medical officers were responsible were recruited from Asiatic or African races. The average British officer or soldier can be very unreceptive of the elementary principles of hygiene, but at least he has been accustomed to good health standards at home. Many of the Asiatic and African troops have never known any such standards, while at some points measures of Western hygiene conflict with their social or religious prejudices.

Particularly in S.E.A.C. it was obvious that merely to treat disease was not enough. The problem was one of prevention. Though there is nothing new in this—it is a principle that has been reiterated over and over again by Army authorities and appears in every manual—it was by no means effectively applied. The figures published for 1943–4—roughly, 300,000 sick and 40,000 battle casualties—tell their own story. If the figures for 1944–5 are published they will probably show a marked improvement, at least in the figures for sickness. If this is so we should attribute the improvement to the vigorous application of three measures—the use of suppressive mepacrine against malaria, the use in forward areas of sulphaguanidine against dysentery, and the general use of D.D.T. against flies. There was, however, no new knowledge available in 1944–5 that was lacking in 1943–4. All that did happen was that supplies were at length made available to the theatre which probably needed them most sorely from the start, and that vigorous efforts were made by administrators to obey their own rules.

Scrub Typhus and Amoebic Dysentery

Neither mepacrine, sulphaguanidine, nor D.D.T., however, is likely to affect the two medical problems which, after malaria and bacillary dysentery, are the most serious—scrub typhus and amoebic dysentery. For an effective weapon against scrub typhus we have had to wait for the fruits of new knowledge in the shape of an effective vaccine. Sulphaguanidine has no counterpart in the treatment of amoebic infections and, despite the proved value of emetine in the acute stages in visceral amoebiasis, cure is uncertain, relapse frequent, and disability may be prolonged. But amoebic dysentery is preventable. Complete preventive measures, of course, were impossible for a division cutting its way along the valleys leading to the Chindwin, but an enormous gain would have been a diminution in the number of cases arising on the lines of communication, which picked off officers and men before ever they reached the fighting zone, or while they were travelling to or from leave and rest areas, or indeed in these areas themselves. The physician may be excused a little bitterness as he realized that the real answer to the crowded dysentery ward was not the drugs which were often in short supply, but properly fly-proofed latrines, clean and fly-proofed cookhouses, cooks trained and disciplined in hygiene, and control of railway stations and such restaurants as were accessible to the troops. An appeal to the D.A.D.H. usually found a man even more frustrated and harassed than the physician. Shortage of supplies, lack of trained personnel, and the impossibility of getting the sappers to do the work with the materials and labour at their disposal largely stultified his efforts. Such shortages, naturally, affected other things besides cookhouses and latrines. One hospital, working at capacity for nine months, had no ablutions for patients. The well was sunk and the pipes laid, but no pump was available.

Problems of Nutrition

Medical officers in the European theatres have had the opportunity, no doubt, of observing malnutrition in many different aspects. In the Middle East it was rare among the troops, although classical scurvy, pellagra, and xerophthalmia were seen in a camp of Libyan prisoners. In S.E.A.C., however, several manifestations of malnutrition appeared. It is arguable that some diet scales were inadequate, but everyone knows that all the items laid down on the scale do not always reach all the troops, and when supply is by air, as so often it was, it is inevitable that shortages and maladjustments should occur. Anorexia, sore tongue, diarrhoea (not that of sprue), and anaemia were common among many British troops evacuated while, and immediately after, Kohima and Imphal were besieged. Nutritional macrocytic anaemia was seen in African and Indian troops. Here again there was no lack of knowledge—the relevant biochemical facts were known and taught well before the war—but there were failures of supply, accentuated in the case of Indians by dietary customs which are only slowly breaking down. One could not help feeling at times that the official mind was beset by the fallacious belief that a diet approximating that to which the sepoy or the askari was accustomed at home was suitable for him under severe campaigning conditions. A moment's thought will dispel such a view. In very many cases he suffers at home from definite malnutrition, for which he pays with a heavy morbidity and mortality, while his output of work, mental or physical, is low. On active service he is expected to put forth the most severe physical efforts and to perform quite unaccustomed mental feats. For example, East Africans with only quite elementary education were turned into signallers, gunners, drivers, and quite good nursing orderlies. The question should be, not to how many calories and to how much protein have these people been accustomed, but how much do they need to do what we require of them?

Materials for Prevention

The Fourteenth once called itself the "Forgotten Army." That its members were forgotten by their friends was never true. That it received little publicity was true but immaterial. That it was starved of supplies of all kinds, including medical supplies, was a truth for which it had to pay a heavy price. It was short, too, of certain categories of soldiers. At one level there were far too few men capable of supervising the constructional work necessary to make proper hygiene possible, with the result that civilian contract labour of a most unsatisfactory type was employed. At a much higher level there were officers with large administrative responsibilities who had insufficient grasp of the problems involved and lacked the drive required to overcome the obstacles of formalism and vested interest standing in the way of improvement. That improvement behind the fighting zone was possible was shown by the comparatively high standard of hygiene achieved by the many fighting units operating under far worse conditions but under vigorous and able commanders.

Meanwhile the problems have not been conjured away by VJ-Day. Troops will inevitably remain in India and in S.E.A.C. for some time, and it is no less desirable to keep them out of hospital now than when fighting was still in progress. Once a man is admitted to hospital, treatment is surprisingly good in view of the difficulties. The chief problem is to prevent him from becoming a hospital case. It is not more hospitals or more medical officers that are required. The latter will remain impotent and frustrated in the face of conditions which they are powerless to alter. In fact, given more transport and some efficient clerical assistance (at present it takes an hour's hard writing to discharge ten patients from hospital) many medical officers could be released. What is required is a better supply of timber, wire gauze, water pipes, and all the material needed to construct hygienic camps, together with the necessary labour. Above all, there are needed in non-medical senior administrative officers a realization of the magnitude of the problem and a determination to solve it. There is a wider problem still. The majority of the world's population lives at appallingly low hygienic levels. Many thousands of them, Africans and Indians in particular, have given to Britain loyal and devoted service for the past five years. Many have died in battle, many more have suffered severe sickness. Distress is world-wide, but these people have a special claim on us. It is true that their economic advancement is essential to any great improvement in health. Besides economic advancement, however, there is needed what medicine alone can give—a real awareness of, and interest in, their problems and an effort, through medical education, to create on the spot the necessary medical services.

EUROPEAN HEALTH PROBLEMS

THE WORK OF U.N.R.R.A.

A meeting of the Royal Sanitary Institute on Dec. 5 was addressed by Dr. ANDREW TOPPING, Director of Health, European Region, United Nations Relief and Rehabilitation Administration. After giving some account of the early troubles of U.N.R.R.A. and defending it from uninformed criticisms, Dr. Topping gave a brief outline of the nutritional position in each country.

Possibility of Famine

The probability of serious malnutrition and the possibility of famine, Dr. Topping said, were the most disturbing features of the European situation. There was reasonable hope that after-war pestilence would, for the first time in history, be averted, but only food in its widest sense would avert starvation. Food reserves were meagre or non-existent, almost everywhere and transport and fuel for transport in short supply. He entered one caveat, however. It was human nature for each country to picture its plight in the grimmest colours, and one must look askance at reports from any country unless checked by impartial observation. In U.N.R.R.A. they were fortunate to have Dr. Sydenstricker, of Georgia, a nutritional expert of world-wide reputation and an extremely sensible man, who went to Paris in January of this year, where he had facilities for examining adults in factories and children in schools in the poorest quarters, and his report was that there was no evidence of serious malnutrition among them and that they could go on for at least six months under the same conditions. That was at variance with the stories current at the time. Again, quite a number of countries disdained staple articles of diet which we in this country had had to put up with during the war—margarine, for example, and soya flour.

Alone of the countries overrun by Germany, Denmark had a fair prospect of adequate diet from her own resources. In Belgium the position was reasonably good, thanks to the strong measures of successive Governments and the fact that the country was small and had seaports. The Dutch people before the war were probably the best nourished in Europe, but just previous to liberation they had a severe starvation period, and it would take them some time to recover nutritional health. Norway was worse off than Holland, for it had very little agricultural land; its fishing fleet, however, had got going again. In France the official rations continued low, with less than 10 g. of animal protein daily for each person. In Italy much rickets was reported among children of poor families, but nutrition in Italy had always been on a low level.

The situation in Greece was most serious, though not nearly so bad as in 1941, when people were actually dying in the streets and nearly all the children had famine oedema. The chief difficulty was in bringing together the producing and the consuming areas; some communities were isolated. In Yugoslavia the situation was very much as in Greece, but the people were extremely self-reliant. The worst nutritional conditions were going to arise in Germany and Austria, where in some cities the present system of food distribution would not suffice to protect the population against the gradual danger of starvation. In Berlin and the Saar the present diet for the normal consumer was 1,000–1,200 calories a day. In the Saar the children were reported to be listless, pot-bellied, and markedly under weight. In the Ruhr the situation was rather better. Germany had an extremely fine agriculture, and the fertility and tidiness of the fields struck him in the early autumn, but the slave labour had now been taken away, the *Wehrmacht* had not returned to the land, and it had been laid down that the Germans must live this winter on a scale very near famine level while the food they produced had to feed the armies of occupation and displaced persons. There was no justification for the sob-stuff that "these wicked Germans are faring better than ourselves."

The Epidemic Situation

Dr. Topping next turned to the epidemic situation, repeating the statement made the previous week by Dr. George Stuart, head of the Epidemiological Intelligence Department of U.N.R.R.A., and recorded in the *Journal* of Dec. 8 (p. 809). The typhus position, he said, was the surprise of epidemiology. Typhus and starvation were concomitants of war, but while there was going to be starvation there was not going to be typhus. In October, 1943, at Naples, for the first time in the history of a typhus epidemic, it stopped suddenly before the seasonal stage at which it would ordinarily decline. This was due to D.D.T. on a large scale and the searching out of contacts and segregation of cases. In Bosnia, one of Europe's notorious epidemic foci, the American Typhus Commission had done extremely good work. Plague was causing some worry in the Mediterranean littoral. In Taranto there had been 26 cases with 12 deaths. The authorities in the Dalmatian and Greek ports were on the look-out for any extension. Typhoid fever on the Continent ordinarily ran a milder form than in Britain, but with the smashing up of water supplies a severe epidemic had occurred in Berlin, though the latest information was that it was under control. Diphtheria was the chief epidemic disease of the war, and in Germany the incidence was rising. Of a large influenza epidemic there was no sign. Tuberculosis had increased in every country, and most markedly in Greece. A mass miniature radiography examination of 500 cadets, ordinarily a healthy group of the population, revealed evidence of active or quiescent infection to nearly 20 times the extent that would be expected in this country.

Finally Dr. Topping paid a tribute to the action of local authorities in Great Britain in releasing men from their public health departments to serve in Europe. U.N.R.R.A. had 379 doctors and 435 nurses in Germany to-day. It also used, of course, so far as possible, the doctors of the different countries themselves. The Germans, when they brought in their slave labour, were careful to bring doctors with it, and so in every assemblage of displaced persons there was a reasonable number of trained or half-trained medical or nursing personnel. He made it clear that U.N.R.R.A. was not operating among the Germans in Germany, nor was it operating at present—though a demand was expected—in Austria. But it was responsible for the hard core of displaced persons, numbering some one and a half millions.

L.C.C. NURSING RECRUITMENT

The London County Council, the largest hospital authority in the English-speaking world, requires immediately 2,500 nurses and 1,600 domestic workers for its hospital service. Lord Latham, the leader of the Council, stated at a meeting at County Hall that the Council welcomed very warmly the new hospital codes recently issued under the aegis of the Minister of Health, the Secretary of State for Scotland, and the Minister of Labour. The codes were already in operation, he said, in the 87 hospitals of the L.C.C.

A recruiting centre for nurses and hospital domestic workers has been opened at County Hall. Representative staff councils are already operating in some of the hospitals, and will soon be set up generally to ensure the free expression of the views of the staffs on matters affecting working efficiency, and general well-being and comfort. Lord Latham claimed that the L.C.C. had been a pioneer in respect of many of the new proposals, notably in the employment of women orderlies to relieve the nursing staff of domestic work.

At the same meeting Mr. Reginald Stamp, chairman of the Hospitals and Medical Services Committee, mentioned that the nurses have separate room accommodation in the nurses' homes, and that notwithstanding the prevailing shortage a 96-hour fortnight is in operation in all but four of the hospitals. It is increasingly the policy to permit the nurses to live out when they wish, and it is hoped that the General Nursing Council will consider whether student nurses, at present required to live in hospital, may not live at home while in hospital employment. The L.C.C. employs 500 male nurses, and men demobilized from the Forces are said to be joining this service in a steady flow. About 150 part-time women nurses are engaged, and the hospitals are doing what they can to enable this class of worker to carry out her hospital service while discharging her domestic obligations. The question was asked as to when the Rushcliffe salary scales would come into force, and the reply was given that this was imminent, and that the latest date would be April 1, 1946. It may be added that the L.C.C. hospitals accommodate about a quarter of a million in-patients a year; 50,000 operations are performed annually; 20,000 births—37% of the whole of the births in London—take place in Council hospitals and institutions; and the number of out-patients approaches one million.

LONDON COUNCIL OF SOCIAL SERVICE

The report of the London Council of Social Service for the year 1944–5 has been published from 7, Bavley Street, Bedford Square, W.C.1. It reviews the work up to the close of hostilities in Europe and outlines plans for the period of transition to peace. The report welcomes the increase of social provision by the State, which, it says, is "in tune with the spirit of the age," but it claims that statutory services need the initiative and enthusiasm of the citizen and voluntary groups, and sets out as a primary purpose of the Council the promotion of partnership at all levels between the public services and the voluntary agencies.

Surveying the everyday work of local councils of social service, the London Council's report pays tribute to their adaptability, resource, and skill in meeting the many emergencies of war, but stresses the need for an effort to rid some councils for an "odd-job mentality," and to enable them to become real centres for local study, planning, and co-operative social action. The London Council itself is rapidly developing into a centre of information and advice for individuals and organizations concerned in the promotion of community centres. The Council is convinced of the potential value of community associations and centres, but thinks that the working out in practice of a policy for their general provision will need careful guidance.

On problems relating to the welfare of old people, the Council has contact with work in 41 boroughs, of which 21 have old people's welfare committees. These committees are regularly supplied with literature relating to old people's homes, welfare schemes, and clubs, and have the advisory services of the London Council at their disposal. The Council is in touch with 47 communal restaurants managed by voluntary bodies; 25 of these restaurants extended their services during the past year to assist men working on bomb damage repairs.

The London Council, in association with the Charity Organization Society, supervises the work of the citizens' advice bureaux in Greater London. From 1940 to the close of the European war more than one and a half million inquiries were dealt with at advice bureaux working under the Council. In the last year the number was 343.801. The report pays tribute to the men and women who came from the Provinces to help in London bureaux during the worst of the flying-bomb attacks, at which time the bureaux worked at full stretch.

PORT HEALTH SAFEGUARDS

While the International Sanitary Conventions are principally concerned with what are known as the "Convention" diseases—namely, plague, cholera, yellow fever, typhus, and smallpox—the new Convention of 1944, with an eye to the circumstances of the immediate post-war period, requires Governments to inform U.N.R.R.A. of outbreaks in their territories of other infectious disease which might constitute a menace as between different countries. It is difficult to foresee whether any epidemic disease, not being one of the "Convention" diseases) might occur in this country in proportions menacing to other countries, and the prospects of such an occurrence may be remote, but the Minister of Health has thought it well to include in the draft Port Health Amendment Regulations, 1945, a provision which would enable preventive measures to be taken in an infected port against the spread of the disease to other countries. Where the port medical officer of health finds a person to be a contact of one of the "Convention" diseases he can at present place the contact under "surveillance," by which is meant that the contact proceeds to his home or other place of destination, but that during the period of possible incubation the local M.O.H. can make inquiries as to his state of health and, if necessary, medically examine him. The new Convention allows Governments, if they think fit, to require a contact who is under surveillance himself to report periodically to the local M.O.H. In the amended Regulations the Minister has not seen his way to introduce the latter system as a measure of general application, but power is reserved by which such a requirement could be imposed at a particular port or ports with the Minister's authority. The new Convention permits of isolation as an alternative to surveillance in the case of unprotected smallpox contacts from an infected ship. A restricted provision for this is made in the draft Regulations where the port medical officer considers that there is an exceptionally serious risk of smallpox being introduced.

The regulations (and the corresponding ones for Scotland) do not involve any basic change in the general procedure of port health authorities. Vessels arriving from foreign ports, however, will have to complete a revised form of declaration of health. New provisions also affect vessels that have called at one or more United Kingdom ports. The wartime ban on the transmission by wireless of health conditions on board incoming ships has been lifted by the Admiralty, and this will help port health authorities to make prompt arrangements for preventing the spread of ship-borne infections.

Nova et Vetera

BENJAMIN RUSH, 1745–1813

"Medicine is my wife and science my mistress"

The Sydenham of America; the American Fothergill; the American Hippocrates; the patron saint of American psychiatry; the hero-physician of the Philadelphia plague; the most distinguished physician America has produced; the great patriot whose signature follows that of Benjamin Franklin on the Declaration of Independence; treasurer of the U.S. Mint; founder of the American Anti-Slavery Society—these are some of the many confused and almost legendary associations which crowd upon the commemorative mind on the two-hundredth birthday (Dec. 24) of this dynamic and picturesque personality. Each association is like a frame, large enough to hold a separate painting of the man, each a record of giant energy and often of true greatness.

The same apostolic vehemence which animated his politics dictated Rush's medical and social crusades. He raised his voice against the evils of strong drink, advocating establishments for the cure of alcoholism, urged penal reforms, and sponsored advanced education for women. He loved to tread untrodden paths, for he saw far in advance of his age. But the permanence of his fame rests essentially on his medical achievements.

A keen and accurate observer and an inveterate note-taker, Rush was one of the first to emphasize the association between infected teeth and arthritis. His descriptions of focal sepsis and of cholera infantum are among the classic texts of medicine. His excursions into psychiatry have won him the affectionate title "Father of American Psychiatry," even though his classification and theories of mental diseases, and many of his therapeutic measures, have long since grown obsolete. He gave the first comprehensive course in psychiatry in America, and his *Medical Inquiries and Observations upon the Diseases of the Mind,* published the year before his death, was the first American textbook on that subject. He stressed the value of occupational therapy, hydrotherapy, and music, and was a pioneer in the humane treatment of mental patients. Rush was one of the most ardent bleeders in the history of medicine, and ironically his death is alleged to have been hastened by injudicious bleeding. Like many men of genius he was a victim of tuberculosis.

It is difficult to come to grips with Rush's unadulterated personality, since this was compounded of so many conflicting and incongruous elements: religious zeal, culture, charm, intolerance, stubbornness, tactlessness, aggressiveness, conceit. An individualist always, he made admirers, friends, and enemies with equal ease. An elegant and forceful speaker with a beautiful voice, a magnetic teacher, and a felicitous writer delighting in classical allusions and entertaining anecdotes, like Sir James Paget he had so disciplined himself that in the buzz of household noises he could read or write with perfect concentration. Naturally dignified in appearance, with a long thin face, high forehead, aquiline nose, firm mouth, and piercing eyes beneath heavy brows, Rush dressed with fastidious care and elegance. W. R. B.

Reports of Societies

SENSE AND SENSIBILITY IN THE TREATMENT OF CANCER

In the Section of Surgery of the Royal Society of Medicine on Dec. 5 Mr. ERNEST FINCH delivered his presidential address, which, with apologies to the shade of Jane Austen, he entitled "'Sense and Sensibility' in the Treatment of the Cancer Patient," following upon Sir Alfred Webb-Johnson's Bradshaw lecture in November, 1940, which was entitled "Pride and Prejudice."

Mr. Finch began by saying that, with the exception of cardiovascular disease, cancer was the chief cause of death in this country, the Dominions, and the United States. In England and Wales in 1941 there were 68,974 deaths from cancer, 61,814 of them being from carcinoma. Every year 7,000 women died of breast cancer. After outlining the provisions of the Cancer Act, 1939, which had passed into legislation almost unnoticed during the preoccupations of these years, he drew attention to some figures published by the Ministry of Health in 1939 showing that in a sample of 3,303 cases, 2,420 (73%) had gone untreated. It was estimated that for every proved case of cancer there were five or six sufferers. Patients were not diagnosed early enough and the treatment given—the first treatment being all-important—was not always adequate. The cancer patient should receive treatment only from physicians, surgeons, and specialists of the required degree of training and experience. Not sufficient use was made of past experience, and experiences were not pooled as they should be. One statistical inquiry had shown that between 80 and 90% of five-year cures of the disease was obtained if treatment was afforded in the early stage. The need was for a regional centralized organization. Methods of standardizing treatment by dividing cancer into various stages had proved unsuccessful; each case must be individually studied. The treatment should be assessed by the surgeon, physician, radiotherapist, and pathologist on a consultative basis, with the biochemist and biophysicist ready to afford any necessary assistance. The co-operation of the patient and his friends must also be obtained and maintained to the end. This was the ideal which he had termed "sense and sensibility."

Enlightenment of the Community

Education both of the community and of the medical profession, Mr. Finch continued, was necessary. Here he referred to the methods of propaganda and education employed in the United States and in some of the Dominions. The objection had been made to some of the public advertisements and leaflets that they were likely to create cancer-dreading neurasthenics, but figures which he showed suggested that they had been effective. One apparent result was that an increasing number of people sought the help of the diagnostic clinics on a slight suspicion of something abnormal, instead of only when the disease had reached a more advanced stage. Thus in Georgia in 1937 the proportion of those visiting the clinics who were found to have a definite malignant disease was 81.2% whereas in 1942, after these methods had begun to operate, the proportion was only 59.5%. It was claimed that in the United States as a result of the education of the community the average period of delay by the patient in consulting the doctor after noticing the first symptom had been reduced from 6.5 months in 1936 to 5.3 months in 1936-9, 4.6 months in 1939-41, and 3.2 months in 1941-4. The delay between consulting the doctor and visiting the clinic was diminishing, and as for the third frequent period of delay, that between visiting the clinic and starting treatment, 66% of the patients now began treatment within one week, and within four weeks 90% had started treatment. So far as he was aware there was only one effort of this kind made by a public health authority in this country—a leaflet by the medical officer of health for Nottingham. It was important in all such efforts not only to give information but to sustain morale. The recital of serious facts must be accompanied by hope and encouragement.

The education of the profession was also important. The student left his school with a definite picture of the final stage of cancer and a list of innocent conditions which might simulate cancer. Was it any wonder that he applied his knowledge to reassuring his patients and giving them confidence that no cancer was present? The practitioner saw relatively few cases and had little opportunity of improving his knowledge. When he saw a lump in the breast, with no fixity, no retraction of the nipple, and no palpable lymphatic nodes in the axilla his training led him to think and say that it was chronic mastitis or some relatively innocent condition. The textbooks, Mr. Finch thought, might be revised and stress early symptoms rather than late. Each case merited individual study, and they should not talk of "treating cancer" but of treating the cancer patient. The practitioner must be made an integral part of any scheme and be kept informed of the results obtained.

He then sketched plans for a system of regional and co-operating centres. The staff of such centres should be large enough to enable them to have leisure for that clear discernment and contemplation which was necessary in this field. There were at present only two main methods of treating cancer—namely, surgery and radiotherapy, though biotherapy loomed on the horizon, and it seemed likely that endocrinology would play an increasingly important part. In the regional and co-operating centres the surgeon, the radiologist, and the pathologist would meet. The regional central headquarters would, if possible, be based on a university, and towards the periphery of its area there would be the co-operation centres, each serving a population of perhaps a quarter of a million, and between these there would be surgical centres. Standards of competence were necessary for dealing with cancer, and only the profession itself could define them; by frank discussion it might reach unanimity. A pooling of experience and the dissemination of the results of research among all concerned were also essential.

PREGNANCY IN A UTERUS BICORNIS

At a meeting of the North of England Obstetrical and Gynaecological Society, which was held in Manchester on Nov. 19, Dr. R. M. CORBET reported a case of pregnancy in a uterus bicornis bicollis, the type described by Munro Kerr as "pseudo-didelphys." The patient, aged 21, first went to hospital because of dyspareunia and sterility. Examination showed a vertical midline vaginal septum reaching from the vault to within a short distance of the introitus. The right vagina was larger than the left. Two uterine bodies could be palpated bimanually, and at the top of the right vagina there was a cervix, but lack of dilatation prevented adequate examination of the left vagina. Removal of the septum and salpingorrhaphy were recommended, but the patient did not return to the hospital until she was pregnant. This occurred in the right horn. She was admitted to hospital with cramp-like pains and bled three weeks before she was due; the same night a decidual cast was expelled from the non-pregnant horn; no contractions of the pregnant horn could be felt. She was discharged, but ten days later was readmitted in labour and in five hours gave birth to a living female child of 5¼ lb. There was no obstruction by the non-pregnant horn or post-partum haemorrhage, most common complications of this condition. This case showed that the horns of a uterus "pseudo-didelphys" could act independently, and suggested that the onset of labour could not entirely be due to a change in the hormone balance.

The annual meeting of the Midland Tuberculosis Group was held in Birmingham on Nov. 24, when 20 members were present. It was decided that meetings should be held bi-monthly on Saturdays at 3.15 p.m. and that invitations should be sent widely in order to extend the basis of the Group. Drs. J. E. Geddes and S. Deaner were elected president and secretary respectively.

The second meeting of the Italian Society of Tropical Medicine and Hygiene will be held in Asmara early in 1946, with the aim of letting Eritrean doctors, veterinarians, and biologists make contact with their colleagues of neighbouring countries and discuss scientific matters. The meeting will last 4 or 5 days. All Italian and foreign colleagues are invited.

Correspondence

Tropical Medicine

SIR,—In his presidential address to the Royal Society of Tropical Medicine and Hygiene, as reported in the *Journal* of Dec. 1 (p. 774), Dr. C. M. Wenyon has rightly expressed great concern about the provision of facilities for dealing with tropical diseases and the teaching of tropical medicine in the future. He suggests that the re-establishment in London of a tropical medical centre "would restore the position formerly held by this country in the field of tropical medicine, would be a monument to the many pioneers who devoted themselves to the study of tropical diseases, and would be a centre of tropical medical activity worthy of the British Empire."

We believe that Dr. Wenyon has understated the case. The time has come for the development of a scheme of national and imperial conception which would envisage the establishment of tropical medical centres not only in London but wherever they are most urgently needed and can be maintained. One of the most immediate needs in this country is adequate accommodation for sick persons coming from the Tropics. The establishment of a tropical medical centre in London would not, in our view, solve the problem. While, unhappily, the facilities for dealing with tropical diseases in London have declined during the war, as stated by Dr. Wenyon, those in Liverpool have been considerably expanded and continue to flourish vigorously. Since the outbreak of war the staff of the Liverpool School of Tropical Medicine have treated over 5,000 in-patient and 12,000 out-patient cases of tropical disease, and concurrently have engaged in an active research and teaching programme.

Personal experience in dealing with such large numbers of patients has taught us that a disadvantage of their concentration in a single centre—i.e., that in Liverpool—has been the enormous area (virtually the whole country) that has had to be served. We are convinced that centralization of such clinical facilities in Liverpool, in London, or in any other single locality in peacetime would be impracticable and not in the best interests of the patients. Dr. Wenyon's plea for the establishment in London of a tropical medical centre as the means of forwarding the best interests and the fame of British tropical medical activity does not, therefore, go far enough. The vitally important matter of providing proper accommodation for cases of tropical diseases in this country must not be settled without taking into consideration such matters as the localization of mercantile and tropical interests in Britain. Such interests are centred mainly about the great ports, and in this respect Liverpool, which is the terminus and home of a very considerable volume of traffic and of trade with the Tropics, shares with other ports the importance of London. Tropical medicine is at present taught in both Liverpool and Edinburgh, as well as London, and we consider that when hospital medical centres are developed in Britain they should be built up in the first instance about these schools, so that each could play its part in the advancement of tropical medicine and the training of personnel for the Colonial and other medical services and for the staffing of the Colonial universities proposed in the Asquith report.

An imperial scheme for the furtherance of tropical medicine in all its bearings—the treatment of cases in this country, planning and teaching with a view to the treatment of indigenous peoples, fundamental research, etc.—can only be truly representative and worthy of our national responsibilities and opportunities if it takes the above facts into account.—We are, etc.,

Medical Future of the Colonies

SIR,—Much credit is due for your objective and well-informed leading article on the medical future of the Colonies (Nov. 17, p. 693). It would be a pity if what ought to serve to open the eyes of the Mother Country to the physical conditions of colonial peoples should, in the event, merely arouse sectarian feelings, as seems to be the case in the correspondence columns of the Dec. 1 issue (p. 781).

I am myself a West African. I have just returned from a five-months tour of British West Africa under the auspices of the Colonial Office and as the guest of the West African Governments, in the course of which I covered pretty thoroughly as much of the four Colonies as could be done by ship, ferry, rail, aeroplane, and motor car. Everywhere I paid particular attention to health conditions and medical facilities.

No one who has the courage to face the facts will deny that the statements contained in your leader are correct, and, what is perhaps more to the point, balanced. Least of all is there any disposition in Government circles to shirk the issue. The responsible officials are alive to the situation and need encouragement. The fact is that the problems are immense and extremely complex, embracing as they do not only the provision of hospitals and medical personnel, but agricultural, economic, educational, and political considerations. I am afraid your statement in the last paragraph that "these reforms are suggested only for European medical officers" reveals a fundamental weakness in what is otherwise a useful presentation of suggestions widely accepted. No one who knows the Colonies to-day openly admits to a dichotomy as between European and non-European medical officers. In fact, of course, in West Africa the Colonial Medical Service is restricted to Europeans, and Africans, when there are vacancies, are appointed as medical officers special to each Colony. But this is a state of things against which so much determined and continued protest has been made that a commission has been appointed to inquire into the whole range of conditions of service of Africans and Europeans in the entire Civil Service, including the medical departments. Personally I shall be extremely surprised if the service is not unified as a result. The health problems of the Colonial Empire cannot properly be tackled by Britain *for* the Colonies. This is not only impracticable but cuts against British political philosophy. It can only be done by the Colonies *with* the sympathetic assistance of Britain.

The number of doctors needed to staff anything approaching a well-run service is so high that it cannot possibly be met by doctors recruited from Britain, especially in view of the needs of the British people. On the other hand, although for about eighty years West Africans have been coming to Europe to qualify in medicine (a great-uncle of mine did this at Oxford in the 1870's), yet it costs about £2,000 for each one to spend the necessary six or seven years in training in this country for the purpose. The result is that in all British West Africa to-day (population of 25 millions) there are some 200 African and 200 European doctors, all with British qualifications and on the *Register* of the General Medical Council.

Obviously two steps are urgently necessary—namely, to produce a large number of properly trained general practitioners in the near future to man the Government medical stations, and, at the same time, to train a minority of consultants in Europe. Steps are being taken in both these directions. The Gold Coast for about five years has been giving a small number of free medical scholarships tenable in England, while there are about eighty other private medical students from the other three Colonies at present in England distributed in the various medical schools. Within the next two or three years it is proposed to establish a West African University at Ibadan in Nigeria, at which, among other things, a complete medical training recognized by the G.M.C. and leading to the degrees of London University will be provided.

Specialists will have to be trained in Europe, however, not only for the consultant section of the service but also to provide part at least of the teaching personnel of the university. The present suggestion of the Asquith Commission is for the staff from professors down to be sent out from Britain on special terms. This will meet a great need, serve to maintain a high standard, and also to retain contact with the progressive traditions of Britain. At the same time there are a number of African youth of both sexes in this country who for some years have been undertaking, at their own expense, extensive postgraduate training and qualification in medicine, surgery, midwifery and gynaecology, child health, psychological medicine, ophthalmology, physiology, and anatomy, and responsible opinion naturally expects that they will be given opportunity to serve their country in senior posts.—I am, etc.,

Newcastle-upon-Tyne. R. B. WELLESLEY COLE.

"Geomedicine"

Sir,—As a practitioner living in a subtropical country I read with the greatest interest Dr. Macdonald Critchley's Croonian Lectures on "Problems of Naval Warfare under Climatic Extremes" published in the *Journals* of Aug. 4, 11, and 18. The author is certainly right in his assumption that hot climate is not the sole cause of the manifold symptoms described as "tropical neurosis." Two questions as posed by him require elucidation: (1) whether the same psychiatric features occur in tropical civilians whose homes and families are on the spot; and (2) whether meteorological and clinical fluctuations run parallel. Now from my experience in Palestine I would not hesitate to answer the first question in the negative and the second in the affirmative.

This country represents perhaps the biggest laboratory for studies concerning adaptation of white people to new climatic and environmental conditions. Palestine is situated in the warm temperate ("subtropical") zone and has many climatic and geographical peculiarities—e.g., hot and humid inland valleys, dry and arid plateaux, hills of 3,000 ft., and a unique depression of 1,200 ft. under sea level. It has furthermore an immigrant population of about half a million, born and brought up in Europe, who have to live and to do hard manual work under climatic and social conditions (changing from urban life and mercantile or professional occupations to farming, fruit-growing, fishing, factory work, etc.) to which they are entirely unused. It is obvious that individuals living for a specified period in tropical or subtropical regions as civil servants or soldiers, without the comfort of home and family life, without any liking for the country and the job they are doing, are apt to develop nostalgic reactions and suffer from neuroses. The same does not apply to settlers, who come to a new country of their own will, desirous to begin a new life and to make the most of it. They will probably suffer sometimes from heat or moisture or from dry desert winds, but not from psychic disturbances. A central Academy of Geomedicine or Climatology as suggested by Dr. Critchley, "wherein all research—medical and scientific—could be undertaken," may prove a most important instrument for studying the problems of settlement of the white races in colonial territories of the Empire and the Dominions situated in hot zones. These problems are certainly vital, not only for the British Empire, but for other countries—including mine—which are dealing with immigrants of European origin.—I am, etc.,

Medical Superintendent.

Rothschild Hospital, Haifa.

Losses of Polish Medicine

Sir,—In connexion with the appeal for medical books for Poland published in the *Journal* of Nov. 10 (p. 676) by the Polish Medical Association in Great Britain, I should be very grateful to you if you could publish the following official information which has just reached me from Dr. Stanislas Konopka, Director of the Department of Science and Publications of the Ministry of Health in Warsaw. This information concerns the material and cultural losses suffered by Polish medicine during the war years.

"The war twice fought on Polish territory and the occupation of Poland during the years 1939–45 brought destruction to every field of cultural and economic life. The cultural losses must be placed first in importance because in the majority of cases the losses are irretrievable, considering the losses of museum collections, archives, and libraries. According to provisional estimate, as far as Polish medicine is concerned, Poland has been deprived of 70% of the equipment of scientific institutes, laboratories, clinics, and hospitals; in Warsaw the buildings too have been destroyed. Eighty per cent. of the medical libraries and museum collections in Warsaw have been destroyed or burnt.

"Before the war the main sources from which Polish doctors derived their professional and scientific knowledge were the university libraries and the special medical libraries. To the greatest Polish libraries belonged the Library of the Warsaw Medical Association, founded in 1820, which contained 67,000 books and medical papers, among them valuable prints from the sixteenth to eighteenth centuries. The second, although much larger library, founded in 1921, was the library of the Military Medical Training Centre. This library was a most active one; it comprised 115,000 volumes, was lending books all over Poland, and possessed a department of bibliography, sending on request bibliographies from every field of medicine and publishing Polish medical bibliography. The annual turnover was fifty to sixty thousand books. Besides these two libraries there existed many smaller ones, such as the library of the Chirurgical Society, Gynaecological Society, Society of Hygiene, etc., and libraries of university clinics and institutes. Of all these libraries only the ruins remain to-day. In Cracow and in one or two other provincial centres the libraries have been partially saved. In Warsaw, however, only the libraries of the ophthalmic, paediatric, and gynaecological clinics have been, to some extent, preserved. Altogether Warsaw lost irretrievably, mainly through fire, twenty-one medical libraries comprising over 550,000 volumes. There is no trace left of the rich museum of the history of medicine. It possessed over 16,000 items, such as old medical instruments, medals, paintings, and valuable collections of old medical documents, manuscripts, and prints.

"Many of the Polish publications, even of the most recent date, have perished, and they will be considered as rare books. During the fighting in Warsaw all the publishing firms and their stocks were lost. This loss is all the more painful as Warsaw was the main publishing centre of medical and scientific books. Only a few private libraries belonging to medical men remain.

"This great dearth of Polish medical books has been increased through the German order, published in 1939, forbidding the publication of any Polish books or papers, including all medical books. The Germans, as is well known, also closed all universities. The German doctor for the City of Warsaw, Dr. Schrempf, published an order—*die wissenschaftliche Arbeit wird streng gestraft*. The Germans saw that this order was strictly enforced by imprisoning many Polish doctors and scientists or putting them into concentration camps from which only 10% came back. The losses in medical personnel will be realized by comparing the number of doctors practising before the war in Poland—14,000—with the number of doctors registered at present—6,800.

"Before the war there were appearing 75 to 82 medical periodicals and journals; practically all the stocks of these have been destroyed. During the war their publication was forbidden and, needless to say, Poland was deprived of access to all foreign medical publications. The only professional medical paper which was appearing in Cracow during the German occupation, and published in Polish, was a paper giving information about the new German sanitary orders and regulations.

"In spite of all the persecutions and destruction brought about by the occupation and fighting the Polish doctors have not given in to despair. Scientific institutes, laboratories, and libraries are being rebuilt and organized. Medical schools in Warsaw, Cracow, Posnan, Lublin, Lodz, and Wroclaw have once more started to function. A new medical school in Gdansk has been established. Through the initiative of the Ministry of Health the main medical library has been restarted and a net of medical libraries in other Polish towns. The publication of medical books has revived. In Warsaw the medical Institute of Science and Publications has been opened. Its main purpose is the printing of medical books and textbooks. Polish medicine, which is well known through the names of Sniadecki, Dietl, Neusser, Bieganski, Mikulicz-Radecki, Babinski, Cybulski, Popielski, Dogiel, Danysz, Nencki, Szymonowicz, Teichman, Curie-Sklodowska, and others, wants to take part again in the progress of medical science. Without, however, the re-establishment of ties with Anglo-Saxon scientists and writings as well as with other nations—French, Russian, Scandinavian—it is impossible to start further work.

"Polish medical men and scientists appeal to their colleagues abroad for help in the re-equipment of libraries with books and periodicals. To facilitate and co-ordinate the help given medical committees for scientific help for Poland have been set up in New York, Moscow, Paris, Stockholm, and Zürich. In London the work is centred in the Polish Medical Association."

Leon Dmochowski.

Glandular Fever and Infectious Mononucleosis

Sir,—Dr. T. S. Eimerl (Nov. 24, p. 743) is somewhat hard on Dr. Gerald Slot and Major F. D. Hart in his criticisms of their article on glandular fever with neutropenia. Dr. F. Muller has already pointed out (Nov. 17, p. 702) that the occurrence of neutropenia has long been recognized, and, indeed, it is by no means uncommon in cases clinically severe. But Slot and Hart were over-seas, we believe, at the time and had only limited access to the literature.

Dr. Eimerl is surprisingly astray on his principal point. He states: "The two terms"—namely, infectious mononucleosis and glandular fever—"are by no means synonymous and should not be used in that manner." They are, in fact, used strictly synonymously. When Sprunt and Evans published their cases of infectious mononucleosis in 1920 they were unaware that there was any connexion with Pfeiffer's *drusenfieber*. When we published our cases in this country a few weeks later (*B.M.J.*, 1921, **1**, 100) it was as a feature of glandular fever. When the proofs of our article were in our hands we read the communication of Sprunt and Evans for the first time, and could only insert an indication that we believed it referred to the same entity. The result has been that in America the term "infectious mononucleosis" is used invariably and solely, while in Britain both terms are in use as synonyms, glandular fever being more commonly but not invariably employed. On the Continent "glandular fever" is often applied to the disease in children and "infectious mononucleosis" to the disease in adolescents and adults, but the identity of the two forms is accepted. Anyone who reads the literature under the impression that glandular fever and infectious mononucleosis are different conditions will arrive at an unfortunate state of confusion.—We are, etc.,

E. B. MORLEY.

Anaesthetic Risks

SIR,—We have read the letter of Dr. E. Falkner Hill (Nov. 24, p. 746) and feel that his assertions are unjustifiably sweeping. He compares alcohol with ether and chloroform and argues that general anaesthesia is undesirable because changes in the cerebral cells can be demonstrated in chronic alcoholics. We might perhaps define a chronic alcoholic as one who drinks to excess more or less daily over a number of years. On the other hand it must be extraordinarily rare for a patient to have more than a score of general anaesthetics throughout a lifetime.

For our part, having due regard purely to the after-effects, we would prefer a skilfully given general anaesthetic rather than suffer the "hang-over" associated with alcoholic over-indulgence. Perhaps the greatest advance in anaesthesia is that, having more drugs at our disposal—such as the short-acting barbiturates, cyclopropane, N_2O, etc.—we are able to administer anaesthesia with minimal after-effects. It is rare to find patients complaining of headache, nausea, and vomiting following the use of the above-mentioned drugs. On the other hand these symptoms appear to be common if we study the condition of those who fail to temper enthusiasm with discretion where alcohol is concerned.

Dr. Falkner Hill also states: "Anaesthesia is generally supposed to be due to a process of suboxidation" and that "the anaesthetic, like Horatius, holds the bridge between the outside of the cell and the inside." Admittedly this is the generally accepted theory, but it may be, however, that cell activity is diminished to such an extent that the O_2 requirements are extremely small. If the latter view is accepted there is only a relative suboxidation due to the diminished requirements of the cell, and as such is surely unlikely to cause any cell damage.—We are, etc.,

Acute Yellow Atrophy after Trilene Anaesthesia

SIR,—I have been most interested in Major K. N. A. Herdman's report (Nov. 17, p. 689), and the subsequent letters by Drs. Philip Ayre and Clifford Wilson (Dec. 1, p. 784). Dr. Ayre attempts to incriminate pentothal by quoting Adriani (*The Pharmacology of Anaesthetic Drugs*, 1942) and Langton Hewer's *Recent Advances in Anaesthesia* (p. 128). On referring to the latter I find that Langton Hewer refers to "Reynolds, C., *et al.*, *Anesth. & Analges.*, 1938, Nov.–Dec., p. 357" and "Vaizey, J. M., *Brit. J. Anaesth.*, 1938, Jan., p. 55" in his reference to the toxic effects of pentothal on the liver. These reports were published when pentothal anaesthesia was in its infancy, and a great deal of research and clinical investigation has been carried out since then, and later work tends to prove that pentothal does not produce any liver damage.

Kenneth Heard of Toronto writes in *Anesthesiology* (Sept., 1944, **5**, 450): "Damage to the liver would seem to be one danger signal, since it is apparently accepted that pentothal is broken down, at least to a certain degree, in that organ. Clinically, we have *not* found that to be the case"; and further: "We have seen no post-operative complications which appeared attributable to the pentothal, even in deeply jaundiced patients." R. Charles Adams in *Intravenous Anaesthesia* (1944, p. 474) writes: "It appears to be doubtful that the intravenous administration of a thiobarbiturate, such as pentothal sodium, for anaesthetic purposes, causes any appreciable damage to the liver or increases damage already present." Later experiments still are quoted by Masson and Beland in *Anesthesiology* (Sept., 1945, **6**, 490). They class pentothal among the barbiturates that are "possibly detoxicated in all the tissues of the body but not to any great extent in liver or kidney."

From my own experience and from the above quotations I do not think the 0.8 g. of pentothal given in Major Herdman's case could have caused the liver damage and that some other cause should be sought. Dr. Wilson's idea of homologous serum jaundice seems a very possible explanation if plasma or serum had been administered. My main concern in this letter is to exonerate pentothal from being considered a possible cause of the liver damage.—I am, etc.,

Cardiff.
A. HUGH MUSGROVE.

Spinal Analgesia

SIR,—I read with much interest the article by Mr. W. A. Fairclough (Dec. 8, p. 801) concerning sixth nerve paresis as a complication of spinal analgesia. I have advocated and given spinal analgesics in suitable cases for many years, and stressed their value in a Hunterian Lecture in 1929 (*Lancet*, **1**, 375). I have notes of three cases of ocular palsies and one of permanent incontinence of urine which afflicted a man with an inoperable carcinoma of the rectum. At that time I used concentrated solutions of various kinds, and I note that spinal percaine 1/200 was used in the ten cases reported by Mr. Fairclough.

For the past five years or so I have only injected intrathecally spinal percaine 1/1,500, and have had no ill effects. The solution is of a lighter specific gravity than that of the cerebrospinal fluid, so the patient is tilted with the head downwards, which also assists in counteracting shock. Fourteen c.cm. is adequate and safe for upper abdominal operations, 8 or 10 c.cm. for appendicectomy or a hernia, and 3 c.cm. for an infant's intussusception. I am of the opinion that a dilute solution suffuses along the dural sheath more readily than does a concentrated preparation, and is less likely to be absorbed rapidly with toxic effects or to cause complications by over-action on a single spinal nerve or localized area of the spinal cord.—I am, etc.,

London, W.1.
R. J. MCNEILL LOVE.

SIR,—May I add to Mr. W. A. Fairclough's ten cases of abducens paralysis following spinal anaesthesia (Dec. 8, p. 801) three other cases originating in the same way which I came across in the last few years.

The first was of a man who had suffered from enuresis and impotence since having a cystoscopy under a spinal analgesic. He was certainly not a neurotic type and I believe his complaint was genuine. Next came a patient with the story that he had never been able to pass a decent motion since being operated on for piles. I expected to find a stricture, but instead discovered that he had a lax sphincter and a ballooned rectum, on which straining produced no effect. "Had he been put to sleep or . . . ?" "No, he had had a needle in the back." The last patient gave a similar history, and volunteered the information that he had to use a finger to get any evacuation at all. The findings were the same as in the previous case.

Unfortunately I had no means of knowing what drug was used or how it was administered, but I have no reason to suppose that there was any departure from routine. And this makes the matter more serious than it might otherwise be, though it was serious enough already in all conscience that three young men should be so disabled. We can guard against introducing infection into the spinal canal or damaging the intervertebral disks with the tip of our needle, but how can we avoid sequelae which we do not often know about, much less understand?

I have heard of similar cases from colleagues and believe them to be not uncommon. Common or not, they deserve ventilation.—I am, etc.,

London, W.1.
STEPHEN POWER.

Spinal Analgesia in Operative Obstetrics

SIR,—The value of Dr. Louis Resnick's article on spinal analgesia in operative obstetrics (Nov. 24, p. 722) would have been enhanced had he indicated that this technique was the optimum procedure in each individual case of his series. The safety factor is of prime consideration in the choice of any anaesthetic technique, and it is recognized that the choice of spinal analgesia is justified on this score in many cases.

If, however, the article in question be interpreted as an invitation to obstetricians to discard other anaesthetic agents in preference to spinal block, further convincing argument is necessary. If it merely seeks to demonstrate what can be done by spinal analgesia one must thank the author for his efforts and extend one's thanks to those patients who might have been better served by other means but who furnished the material for the demonstration.—I am, etc.,

Salisbury. A. D. H. SIMPSON.

Crooke-Mellgren Cells

SIR,—I note in the *Medical Annual* for 1945 (Wright, Bristol) that, under the section on the pituitary gland, Langdon-Brown and Simpson describe the changes in the basophil cell of the pituitary gland in Cushing's syndrome as the "basophilism changes of Crooke and Mellgren." The changes which they ascribe to Mellgren (1942) were demonstrated in detail by me at a meeting of the Pathological Society at Glasgow in 1941 and frequently mentioned by me in correspondence with other pathologists, including Crooke and Russell. Publication was delayed until I had devised special methods for reproducing photographically the abnormality ascribed to Mellgren. My manuscript was submitted in 1942 and published in 1944 (*J. Endocrinol.*, 1944, **3**, 323), the delay being caused by difficulties in securing colour printing in wartime. The date of submission is recorded in the journal.

I am writing this in the interest of accuracy and because the description of the abnormalities which the writers ascribe to Mellgren was claimed (rightly) by me as original observations in my M.D. thesis (Glasgow University, 1944) and at the Manchester meeting of the Pathological Society in 1943, where I demonstrated the special staining techniques. I have not referred to Mellgren in any of my written work or demonstration as his contribution was unknown to me. It is unfortunate that the writers do not state what Mellgren interpreted the changes as representing, for this is the crux of the problem and is dealt with extensively in my papers.

A somewhat similar situation through wartime difficulties of publishing arose in connexion with alloxan diabetes. By the time the paper from Glasgow was published announcing the production of islet necrosis with alloxan, Glasgow workers had completed the examination of diabetic rats and rabbits up to sixty days' duration, and colleagues had demonstrated similar effects of alloxan on the mouse and dog. Nevertheless the production of diabetics with alloxan first appeared by the hand of American workers, and the claim of the originators was somewhat obscured by references to an earlier work on alloxan by an American chemist who had injected alloxan into animals and studied their blood-sugar curves. While the true facts are generally known in such cases by scientific workers, the medical reviewer is sometimes more concerned with chronological order of publication than with the well-documented and illustrated publications of more worthy contributors. This is especially so on the other side of the Atlantic, where the reviewer's data are often obtained from collected summaries rather than from the original papers. —I am, etc.,

N. G. B. McLETCHIE, Major,
Bangalore, India. Evacuation and Distribution Staff Officer.

Galvanic Stimulation of Denervated Muscle

SIR,—The letter of Prof. H. J. Seddon and his co-workers (Nov. 24, p. 745) with its additional reasoning as to the value of galvanism in the treatment of denervated muscle will be read with great interest.

My doubts on this subject arose during the observation of an assemblage of peripheral nerve lesions in which galvanism was employed in the treatment of denervated muscle. Progress was estimated by the method of Tinel, by the elicitation of formication on percussion over the lower limit of the advancing axons. By serial observations at monthly intervals a fairly accurate estimation of the rate of regeneration could thus be obtained. It so happened that one of these patients, in whom regular gradual regeneration was taking place, sustained a fracture of another limb, and was absent from the treatment of his nerve lesion for a number of weeks. On his return examination by Tinel's method showed the unexpected result that the rate of regeneration had been considerably more rapid during the absence of galvanic stimulation. In several other cases the treatment was interrupted by some extraneous circumstance, and in every instance the records showed an acceleration of the rate of recovery during the absence of galvanism. It should be said that these observations were not planned for the purpose, but were due to chance events during the course of treatment; and also that the records appeared to show that galvanism did not prevent regeneration, but slowed down its rate; and also that there was no evidence that the final result was impaired. Though in no way conclusive, these results appear to merit further consideration.

To give a further instance, in facial paralysis an extremely slow and gradual process of recovery sometimes persists for a considerable period. In several of such cases the effect of stopping galvanic treatment has been tried, and in each such case there has been an apparent acceleration of the rate of recovery, as judged by ordinary clinical examination, the quantitative estimation by Tinel's method not being here available.

In the endeavour to find a hypothetical explanation of these results the different stages must be taken into account. During the re-establishment of the motor end-plates by the delicate terminations of nerve fibres, the katabolic changes induced by powerful and repeated galvanic contractions may well be detrimental; there is here a contrast with the natural process of recovery, in which the gradual increase in the strength of the voluntary contractions is proportioned to the stage of regeneration, the neuromuscular mechanism being thus nursed into recovery. At an earlier stage, when the nerve fibres at a higher level are undergoing regeneration, vigorous galvanic stimulation may exercise an unfavourable influence owing to the repeated movements and disturbance of tendons and muscles in the neighbourhood of the nerve trunk. Finally, long-continued galvanism may cause pain and redness of the skin, and it is believed to cause ionization of deeper tissues; this long-continued irritation may well be inimical to a slow and difficult reparative process. Here arises the question of contractures. It is generally agreed that under ordinary circumstances denervated muscle does not undergo contracture; on the contrary, it tends to elongate (Volkmann's ischaemic contracture is in a different category, and the so-called secondary contracture in facial paralysis is in reality a semi-voluntary contraction of muscles which have partly or wholly regained voluntary power). Though not in accordance with the general experience, Dr. R. E. M. Bowden (Oct. 13, p. 487) states that contracture may occur in paralysed muscle, either early or late in the course of denervation, and gives directions for its prevention. Presumably these cases had been treated by the exceptionally intensive galvanism recommended by Prof. Seddon, and the changes thus set up in the muscle had led to contracture. Further information would here be of interest.

Great interest attaches to Prof. Seddon's exact analysis of problems which usually receive only clinical study, and it may well be hoped that his researches will throw light on the more general aspects of nerve regeneration in addition to those concerning the muscles.—I am, etc.,

Sheffield. R. G. ABERCROMBIE.

Midwife's Responsibility in Placenta Praevia

SIR,—Should the midwife make a vaginal examination in cases of placenta praevia? The treatment of placenta praevia has passed through many different phases: version and extraction, total detachment of the placenta, artificial rupture of the membranes, bipolar version, vaginal packing, metreurysis, Caesarean section, Willett's forceps. Nowadays hospital treatment of all such cases is advocated. It is now almost axiomatic that no vaginal examination should be made before the patient is admitted to hospital. In hospital vaginal examination is performed only after all preparations have been made for any treatment which may be required, either by the vaginal or abdominal route. Such is common medical teaching.

In skilled hands, with suitable use of blood transfusion, maternal results may be good and not vary much, irrespective of the method employed. This is not so with foetal results. It is now clear that when active measures are necessary the best foetal results are obtained either by artificial rupture of the membranes alone or by Caesarean section. In order still further to reduce the foetal mortality it is now suggested, in the report of a meeting of the Section of Obstetrics and Gynaecology of the Royal Society of Medicine (Dec. 1, p. 779), that the patient need not necessarily receive active treatment on the first haemorrhage, and a period of expectancy is advocated to lessen the incidence of prematurity.

Where team work is required it is important for all members of the team to be adequately and suitably instructed in what is required of them. It is my submission that there is a note of uncertainty in the midwife's instruction. As she frequently sees the patient first hers is a great responsibility. Should she make a vaginal examination? Generally speaking she should not, and is so instructed. If the patient is bleeding when she arrives what is she to do? Her textbooks even advocate her rupturing the membranes if the patient is bleeding and if she cannot get a doctor. Should she not be told to empty the urinary bladder by catheter, apply abdominal pads and binder, keep the patient warm and give a sedative; that if she does nothing more *the bleeding will stop*? The patient can have a transfusion when medical help is eventually obtained, after which she can be removed to hospital.

Some examiners at the Central Midwives Board examinations expect candidates to say that *they* (the candidates) would rupture the membranes themselves if the patient continued to bleed and if the doctor summoned failed to arrive. By attempting to do this, however, the midwife is likely merely to provoke an increase of haemorrhage. A midwife "snowed up," and likely to remain so for a week, in a cottage with a bleeding patient might be forced to undertake active treatment herself. But such circumstances are rare, and they should not be allowed to obscure the plan of action to be followed in more usual circumstances.

Not only are pupil midwives perplexed as to how they should answer their examiners, but the sister tutors too are in doubt about the best instruction to give them. Those pupil midwives will retain their uncertainty even when they pass their examination. When they meet antepartum haemorrhage in real practice they will still be uncertain how to act. Now their uncertainty will constitute a maternal danger. In new and laudable efforts to improve the foetal mortality let us not overlook this standing maternal danger.

Are pupil midwives in their training schools ever allowed under supervision to rupture the membranes in cases of placenta praevia? I doubt it. Why, then, tell them to do by themselves out of hospital what they are not allowed to do in hospital even under expert supervision?—I am, etc.,

North Middlesex County
Hospital, N.18.
ANTHONY W. PURDIE.

Treatment of Varicose Ulcers

SIR,—Dr. R. K. Brooks's letter (Dec. 8, p. 816) on the above subject advocates the application of certain creams and ointments to chronic varicose ulcers. He claims good results on a "fair number of cases." I suggest that the pathology of the complaint is ignored, and that the only placebo he offers to the gravitational causation of varicose ulceration is to tell his patients to elevate the limbs for a couple of hours every day. I claim that if his treatment is followed the varicose ulcer patient will be with us for yet another generation. It matters not what medicament is plastered on to a varicose ulcer: the cause must be treated. Failure to treat this cause means constant recurrences of ulceration.

All cases of varicose ulceration require compression treatment. This may be obtained in various ways, and if Dr. Brooks does not like the "elastoplast" technique there are many others. The two-way-stretch bandage is valuable for most cases, but there are many other types. All cases of ulceration need surgical treatment to the incompetent superficial venous circulation, provided the deep veins are in good condition.

If Dr. Brooks were to attend a clinic dealing with vast numbers of varicose ulcers I feel sure he would appreciate my anxiety lest his views were to be adopted. Dickson Wright has done the profession untold good in preaching the true pathology of the gravitational ulcer, which, with proper treatment, can be made a rarity instead of a weighty economic problem.—I am, etc.,

London, W.1.
R. R. FOOTE.

SIR,—Having read Dr. R. K. Brooks's letter on his methods of treating what appears to be no more than a complication of hypostasis, I find no mention of varicose veins, which could hardly be absent in a limb with varicose ulcers. It is my opinion, based on my own cases and on the follow-up of a considerable number of others treated elsewhere on similar principles, that ulcers due to varicose veins will invariably clear up if the cause is effectively dealt with, even without local treatment or elevating the leg. Dr. Muldavin (Dec. 8, p. 816) describes very clearly the principles of treatment to which I refer. Treatment on these lines would seem to offer not only a more rapid cure but one which is usually permanent.

While local treatment may be effective in clearing up ulcers and eczema in the elevated leg, surely this is produced by the diminished hypostasis, due to the position of the limb rather than to any substances applied locally. Ulcers invariably recur when the patient resumes his former existence, spending more time in the erect position. One not uncommon exception to this is the occurrence of a coincident phlebitis, which gives a longer temporary cure but relapses when the tributaries become dilated and incompetent, or the original vein becomes recanalized.

Cure may also be obtained by applying to the limb pressure sufficient to render the veins harmless by flattening—i.e., "elastoplast." Relapse may be avoided by the continuance of pressure —i.e., crêpe bandage. The advantages of pressure treatment over postural in patients who are too old for surgical measures are that it is ambulatory throughout and does not require postures which are liable to embarrass the senile cardiovascular system.—I am, etc.,

Hayle.
P. L. RENOUF.

Artificial Pneumothorax Refill

SIR,—As an "old hand" at artificial pneumothorax I well recall the methods employed in 1918—namely, the anxiety about knowing the pressure within the thorax, the giving of a local analgesic, and the slow running in of the gas. Over a quarter of a century ago Parry Morgan had devised an apparatus whereby the mean pressure could be known the whole time gas was running. This apparatus we gave up in 1920. Fifteen or sixteen years ago there was marketed the Peter Edwards pneumothorax needle and stopcock, which cover all the suggestions made in letters. As to a local analgesic, this has been given up for twenty-five years because people prefer both their induction and the refills without it.

I would like to register my disapproval of the method suggested for refills by most of your correspondents. It is my opinion that to push the needle straight forward without stopping is not good practice. At a refill one should learn to sense the pleura, and in order to do this digital pressure in the intercostal area is desirable, and a firm pressure with the needle, note that one is through skin, through the other layers, and "sense" the pleura. By doing this one is so much happier at an induction because one knows when the pleura is encountered. There does not appear to be any reason for knowing the mean pressure as the air is going in. A rough rule would be to run in—at as high a pressure as one's apparatus will permit and as quickly as one likes—half of the quantity of air taken at the last refill. Take the reading and continue until the pressures are at their optimum.—I am, etc.,

Cheshire Joint Sanatorium,
Market Drayton.
PETER W. EDWARDS.

SIR,—We have followed the correspondence on this subject with much interest and many misgivings. It appears to us that there are but two considerations—that the operation should be safe and that it should be as nearly painless as possible. The greatest danger is undoubtedly that of producing air embolism, an occurrence best prevented by using a type of apparatus that allows a manometric reading to be obtained throughout the instillation of air. Incidentally, if the Lillingston-Pearson machine is used a swing may be obtained during the whole procedure if the manometer is left in the circuit. Thus the use of so cumbrous a needle as that described by Dr. Alastair Allan (Nov. 3, p. 607) or of the elaborate feat of digital dexterity practised by Dr. W. H. Tattersall (Dec. 1, p. 783) may be avoided. Before leaving this aspect of the subject we would utter a word of warning against the manœuvre described by Dr. Paton Philip (Dec. 8, p. 821). While it is admittedly easy to insert the refill needle accurately into the pleural cavity during expiration, with the lung deflated, the dangers of lung puncture and of embolism return with full force as the lung re-expands during inspiration towards the point of the needle, especially if this is of the fine, sharp Morland pattern—a type that we never use.

We are in complete agreement with those of your correspondents who oppose the use of a local analgesic—a practice which very seldom contributes to the patient's comfort yet always adds to his hazards. The chances of sepsis, admittedly small in this connexion but nevertheless present on every occasion when the body surface is punctured, are doubled when two needles have to be introduced. As Dalgleish (Dec. 8, p. 821) has pointed out, there is no guarantee that the refill needle will penetrate to exactly the same depth in exactly the same place as the needle for the analgesic; thus the latter cannot usefully assist in the prevention of air embolism. Furthermore, the use of novocain introduces a new source of risk, since definite, though rare, cases of novocain poisoning have been recorded; a recent fatal example is described by Andosca and Foley (*Amer. Rev. Tuberc.*, Sept., 1945, p. 221).

Concerning the problem of pleural shock, we are of the opinion that no such clinical entity exists. This vexed question has been debated *ad nauseam* in the literature of artificial pneumothorax. For the latest discussion on the subject the reader is referred to the paper by Andosca and Foley, quoted above. Even if there were such a condition it is hard to see how its occurrence could be prevented by the use of a local analgesic, for the needle, itself as liable as the refill needle to produce shock, must penetrate the parietal pleura before that membrane can become fully anaesthetized.—We are, etc.,

B. G. RIGDEN.
PHILIP STEEN.

Red Cross Sanatorium of Scotland,
Tor-na-Dee.

SIR,—During six months, from February to July, 1945, as house-physician at the Brompton Hospital, I did more than four thousand artificial pneumothorax refills. The great majority of the patients at Brompton—certainly more than 90%—prefer not to have a local analgesic; and this is true also at the Chest Clinic at Hammersmith Hospital, where I now work.

Most of your correspondents agree on this point, and they say that providing the needle is sharp and a rapid plunge is made there are few complaints. If there is an adequate pleural space then this technique is safe; but if the artificial pneumothorax is shallow then I believe a local analgesic should be used so that the needle may be slowly and carefully introduced. Otherwise there is a danger of puncturing the lung, and this may be followed by air embolism—an event which one should strive to avoid, however rare it may be. The other indication for giving a local analgesic is—as Dr. H. P. Fernandes points out (Dec. 8, p. 822)—when the patient asks for it. If it makes him feel any happier, then I think he should have it.—I am, etc.,

RAYMOND WILLIAMS.

Chest Clinic, British Postgraduate Medical
School, London, W.12.

SIR,—Dr. C. F. Hawkins is not alone in his belief that local analgesia is unnecessary before giving an artificial pneumothorax refill. I have known several leading physicians who practise an almost identical technique to that described, using the Morland needle. I, myself, and most of my contemporary colleagues used this technique for hundreds of refills at a famous chest hospital. It was usually found that novocain was not required after the fourth or fifth refill. The procedure was always explained to the patient beforehand. It is important to use the same place for refills so far as possible, as this area undoubtedly becomes less sensitive. If, for any reason, it is necessary to change the point of entry I always use novocain on the first occasion.

"Refill patients" become more attached to one particular doctor than any other class of patient I have come across. It is important that this relationship should be fostered in the early stages of the induction of an artificial pneumothorax; the change-over from the use of novocain to doing it without it is then readily accepted. Every patient I have questioned in an out-patient refill clinic was horrified at the suggestion of using novocain for the refills. With novocain there is not only the slight discomfort of the injection but also a more irritating itching two hours later as the numbness wears off.

I agree with Dr. Hawkins that complications are no more frequent in an established A.P. when local analgesia is disregarded.—I am, etc.,

P. McA. ELDER,
Fl. Lieut.

Bletchley, Bucks.

SIR,—I thoroughly agree with the opinion of Dr. C. F. Hawkins in his letter (Nov. 24, p. 742) in every detail. One occasionally meets a patient who is hypersensitive or of a nervous temperament, but even in such cases I find that the use of a local analgesic for a refill after an adequate pleural space is obtained only adds to the patient's discomfort. I use a Morland needle and have been fortunate enough not to have experienced a case of pleural shock so far. Such cases appear to be rare. Like Dr. Hawkins, I shall indeed be grateful to have the views of others.—I am, etc.,

G. M. MAYBERRY.

West Ham Sanatorium,
Dagenham.

Treatment of Early Syphilis: A Warning

SIR,—As far back as Nov. 11, 1939 (p. 974), I suggested in your columns a reliable scheme for the treatment of early acute syphilis. A similar scheme, with or without penicillin, has been used to date for many Service and civilian cases. Penicillin has now taken an important part in the treatment of venereal diseases. It rightly holds the first position as a therapeutic agent for the treatment of gonorrhoea. Gonococcal relapses or failures do occur, but, generally speaking, the results are very good.

I wish, however, to register a strong word of warning against any present tendency to depend on penicillin alone for the treatment of acute early syphilis. The tendency to shorten treatment can be carried too far. We do not want to see cardiovascular and neuro syphilitics turning up at the V.D. clinics some years hence. I can produce definite evidence of failures or relapses in early syphilitics treated by penicillin alone. No doubt other senior venereologists could do likewise. Penicillin alone may cure some cases, but so did a few injections of "606" 27 years ago. Ask any British venereologist what treatment he would prefer himself if he had a chancre or a secondary syphilitic rash. The answer, I think, in most cases would be penicillin *plus* at least one course of ten twice-weekly injections of neoarsphenamine and bismuth. He would also desire blood tests (Wassermann and Kahn tests) and a C.S.F. examination up to three years from the date of infection.

We have now a wonderful opportunity to reduce the incidence of venereal disease in this country. Let us do it thoroughly. Educate the public on the dangers of venereal diseases and, above all, give adequate treatment and tests of cure.—I am, etc.,

C. HAMILTON-WILKIE,
Director of V.D. Services.

Leicester.

Tobacco Smoking and Health

SIR,—In connexion with the recent correspondence on tobacco smoking may I remind your readers of some facts. Stomatitis and pharyngitis (with their associated spitting and hawking) are characteristic of heavy smokers. Cancer, buccal and bronchial, is much more common in men than in women and in smokers than in non-smokers. Bronchus carcinoma becomes more common as the consumption of tobacco increases. I have under my care at present a lady with extensive buccal leukoplakia and a large epithelioma inside the cheek. She has smoked heavily, has been edentulous for years, has not drunk spirits, nor had syphilis.

Tobacco distillate is a tar rich in aromatic substances with polycyclic benzene nuclei, belonging to the same class as those extracted from coal-tar and proved to be carcinogenic. Tobacco tar has high carcinogenic properties (up to 100%) in experimental animals. It is easy to produce epithelioma on the ears of rabbits by painting them with tobacco distillate (Prof. Roffo, "Krebserzeugende Einheit der verschiedenen Tabakteere," *Dtsch. med. Wschr.*, June 16, 1939, **65**, No. 24). The chronic inflammation which can so easily be seen in the mouth and throat of heavy smokers no doubt extends into the trachea and the bronchi, as shown by the experience of anaesthetists who find that heavy smokers are difficult to anaesthetize because of the irritability of and mucus in the respiratory passages, and that pulmonary complications after anaesthesia, from slight cough to pneumonia and atelectasis, are chiefly found in heavy smokers (see Lundy's book on anaesthesia).

Now for prophylaxis. When our children are growing up we should warn them: (1) That tobacco does harm. (2) That they cannot take at face value the statements of smokers about smoking, because many smokers, physicians or laymen, are drug addicts and have lost the power of giving an objective, unbiased opinion about their own habit. The smoker wishes to continue the use of tobacco without appearing a fool or a drug addict. His self-esteem therefore demands that he close his mind to any suggestions that tobacco may be harmful or that it is a drug. (3) That advertisements are designed by clever men to trap young people into taking a drug, that many so trapped will never be able to give up the habit, and that the object of the advertisement is the financial gain of the advertiser regardless of the welfare of the victim. The mechanism of the trap is to show from all points of vantage, day after day, year in and year out, the use of tobacco by types of people who are admired, emulated, and envied by children and adolescents. For the boys the hook is baited by the fine manly picture of an explorer, or soldier in some far-flung outpost of Empire, or of a sailor or sportsman. For the girl the hook is baited by the picture of a beautiful woman, superbly dressed and smoking her cigarette with the utmost poise. To be "smart" is an inducement held out to both boys and girls. The obvious cumulative effect is insidiously and subconsciously to fix in an immature mind the suggestion that if the victim would only adopt the actions and habits of the magnificent being in the advertisement then he would come more nearly to resemble that creature.

If we forewarn and educate our children in this way we will have done our best to preserve them from at least one disease, with its many complications.—I am, etc.,

Sydney. V. J. KINSELLA.

Nylon for Buried Sutures

SIR,—Shortly after reading Mr. Herbert Haxton's article (Jan. 6, 1945, p. 12) on nylon for buried sutures I began using it for all parietal sutures. I can therefore look back on its use for some eleven months, and can make some observations that may be of interest.

My method of tying knots is to hold the long end taut while tying both halves of a reef-knot with the short end in the left hand. Haxton's method of changing hands for the locking half-knot thus did not come easily to me, nor have I used it. I have made up for this by tying four or five half-knots in my habitual manner using both halves of the reef-knot alternately. The resulting knot, unwieldy in catgut as it would be, is quite unobtrusive in fine nylon, and does not slip.

It struck me that there could not be any objection to the use of nylon for the uterus in Caesarean section, but that the more bulky knot occasioned by the use of heavier-grade suture might give rise to peritoneal irritation. This has not been borne out clinically. In common with all abdominal cases, Caesareans are more comfortable *ab initio* than those in which catgut has been used. Hernias are notably more comfortable, and the rehabilitation of all goes on practically without prompting, and with very little need for instruction. In such a short time I have not had occasion to reopen any of my cases, but I have no doubt that Haxton's observation on the lack of tissue reaction is, in fact, the case.

While accepting all that catgut manufacturers say about improvements in their art, I cannot rid my mind of the uncertainty in the lasting qualities of catgut in the presence of tissue digestion, and the feeling of security in the use of nylon is very comforting. I doubt if I shall ever change from it.—I am, etc.,

Dorchester. T. RUSSELL STEVENS.

Pasteurization of Milk

SIR,—I am afraid Dr. Ronald Clarke (Nov. 10, p. 666) has missed the main point of my letter, which should be regarded as a whole. The point I was deploring was the tendency of many doctors to regard good health from a very materialistic and mechanistic point of view. They seem to have divorced it entirely from that mysterious force we call Life, and think of it only in terms of the presence or absence of disease germs, so that all that is necessary for perfect health is to inject some laboratory substance under the skin, or pasteurize our food (however dirty or non-nutritious), and immediately good health is had by all. It is this wrong emphasis which I consider is a serious factor in much of the preventable ill-health of to-day. The general public is led to believe that there are no such things as natural laws of health, and that they can live as unhygienically as they wish and remain in good health if they carry out the short-cuts of inoculation and pasteurization.

It is quite obvious if we look around us that a high degree of immunity against all infections—including tuberculosis—can be obtained by regularly carrying out certain simple matters of hygiene in regard to exercise, fresh air, dietetics, etc., and in adopting a right mental attitude to the adventure of life. These are the things which bring about what has been called "positive health," and should always be stressed when we are trying to cure or prevent disease, whatever our method of treatment.

If now in the question of our milk supply we regard pasteurization as the *final* word in its preparation, we encourage laziness and dirty habits in our dairy workers and overlook the importance of good health in our cattle. Dr. Clarke says "pasteurized sewage is at least sterile, and is probably preferable to tuberculin-tested milk with typhoid bacilli," thus overlooking the fact that sterilized sewage has no food value, and will contain many poisonous substances not conducive to health, even though it may be free from disease germs. Milk, on the other hand, which has come from robust cows and has been handled with scrupulous cleanliness at all stages will not contain typhoid bacilli and will not need pasteurizing; moreover, it will have a very high nutritional value.—I am, etc.,

Slough, Bucks. H. TUDOR EDMUNDS.

National Research into Tuberculosis

SIR,—Dr. George Luntz's letter (Dec. 1, p. 781) raised an issue which no worker in the field of tuberculosis can ignore. It is time indeed that we made a proper appraisal of our present methods of treatment as they can be applied to the sufferer from the most prevalent manifestation—pulmonary tuberculosis. This disease is so treacherous that one never feels secure when giving a prognosis; perhaps one only remembers the unfortunate cases; but they occur much too frequently. The majority of cases that enter sanatoria are not suitable for any form of collapse therapy, and of those cases that are how many benefit from it? Now that these methods of treatment are coming under critical review it is being increasingly realized that they are over-used and, to a great extent, overrated.

If the gloomy side of the picture has been over-emphasized here, it has been done to point the moral—the answer to the problem of tuberculosis has not yet been discovered. Now that we have entered the era of specific treatment with chemotherapeutic substances our hope is that such a substance exists which can be used to cure tuberculosis. No effort or expense should be spared in the attempt at its discovery and we should tolerate no delay. It is a prime responsibility of the medical profession and the Government, in meeting this national problem, to set up a special research unit with this object in view. As Dr. Luntz remarks, the reward will be the gratitude of all mankind.—I am, etc.,

London, N.W.3. S. M. HILTON.

Physical Therapy in Mental Disorder

SIR,—It is now two years ago that you published two letters from me, and many letters from others, on the subject of the new physical methods of treatment of mental disorder, especially electrically induced fits. In these two years a very large number of people have been treated by induced fits: to some harm has been done and some have been "cured." The fact remains, in my opinion, that these forms of therapy have disadvantages, the most serious of which is that false theories of mental disorder are built up round wrong interpretations of the mechanism of these "cures." The medical profession should be reminded from time to time that these treatments are pure "shot-in-the-dark" affairs, and no theory of their action, even when they seem to work, is accepted even by the psychiatrists.

The great example of this bad result of building on other than scientific foundations is provided by the treatment of mind disorder by operation on the brain. In good faith members of our profession are cutting brains about, dividing the associating fibres between the frontal lobes, devising other ways of using their brilliant team work and surgical technique. Yet enough is already known of mental disorder for it to be said that no mentally ill person can ever be made well by operation on a normal brain. In fact, it must be an important part of every leucotomy treatment to see that if the patient gets well enough to go out and do his shopping and go to the cinema he does not also regain the right to vote, or take an active part in the arrangement of our affairs. He is permanently maimed.

I realize that the correct procedure is for us to speed up research into the psychology of insanity and so to provide a scientific basis for mental hospital work, but in the meantime are we to see our countryside littered with "cured" mental hospital patients with permanently deformed brains? And what happens if these physical therapy methods spread to the treatment of criminals? What guarantee have we that a Bunyan in prison will be allowed to keep his brain intact and his imagination free, or, to take a more ordinary case, that a political prisoner should be allowed to maintain his political convictions and his brain.

A new habeas corpus is needed now, a "habeas cerebrum," and very quickly. At any rate I should be grateful if your journal could once again make it possible for it to be said that there is one doctor who thinks the new physical therapy of mental disorder is sociologically dangerous, and that surgical interference with the brain in mental disorders is absolutely never justified.—I am, etc.,

London W.1. D. W. WINNICOTT.

Future of Venereology

SIR,—This is the age of planning, and we as a profession have been duly warned that our future activities will soon be subject to a control which we can only hope will be wise and paternal. The intervening period while our masters are making their plans is a period of difficulty for many young men who are returning from the Services either without a settled appointment or with an appointment which is not in keeping with their added years and experience. In many special subjects these young men are able to bridge the gap and support themselves by temporary registrarships or by research scholarships.

For my own subject—venereology—there is no such provision. Although figures are not yet available, it would probably be conceded generally that, taking all theatres of war, the venereal diseases were the major health problem of the armed Forces of the Crown. It is certain that in some places the problem assumed such proportions that the situation was saved only by heroic energy and improvisation. Many young men of high quality have had much experience in this subject and are continuing to take a deep interest. Some of them have already returned to civil life, and they are inquiring about the possibility of continuing their specialized work. In almost every case the answer has to be discouraging. There are no prospects; nothing is known of plans.

How is one to advise these men? Who are the planners and what is the substance of their plans for the future of venereology? Is it possible that there are no plans, or do the planners share the prevailing illusion that penicillin has provided the answer to all our problems in this respect? It is important that we should know. These young men must live, and if their ability and experience are to be used action must be taken now and not in three or six months' time. By that time the best of them will have made other arrangements. The alternative is to allow this vitally important subject to remain, what it has so often been, the perquisite of the elderly, the unprogressive, and the unimaginative, who practise their obscure routine in some forgotten basement.—I am, etc.,

A. J. KING.

Scalenus Anticus Syndrome

SIR,—As an observer only, I have been impressed by the number of patients suffering from this distressing and disabling condition who have been treated in the Orthopaedic Department of the Luton and Dunstable Hospital and have been cured by a simple operation. The condition does not appear to be well known; many of the patients have been in misery for a considerable time and have attended hospitals, and even neurological units, without benefit.

Briefly, the symptoms resemble those of a cervical rib, starting with brachial pain, accompanied by tingling and numbness in the hand, and associated with pain behind the shoulder. A typical case is as follows: (1) There are the symptoms of a progressive "idiopathic" brachial neuritis. (2) The patient is young to middle-aged. (3) In right-handed people only the right arm is affected. (4) The sufferer has been doing some extra or unaccustomed manual work. (5) There is no neuritis, fibrositis, or arthritis elsewhere. (6) The condition is not affected by administration of vitamin B_1, and is made worse by the usual massage and electrical treatment. (7) Frequently the patient has been diagnosed as neurotic, hysterical, malingering, etc. Radiological examination shows no bony abnormality such as cervical rib, osteo-arthritis of cervical spine, etc. So far as possible foci such as diseased teeth, tonsils, or sinuses have been excluded.

I am informed that the injection of a local anaesthetic into the scalenus anticus muscle quickly relieves the pain and confirms the diagnosis. The operation is simple and consists in cutting the scalenus anticus muscle and cleaning the fibrous connective tissue from the cords of the brachial plexus. I believe that in about 95% of cases relief is obtained very rapidly, and that this is complete, except that some patients still complain of the pain behind the shoulder.—I am, etc.,

Luton, Beds. HUBERT O'MEARA.

Staffing of County Hospitals

SIR,—The Council of the Association of Anaesthetists of Great Britain and Ireland is disturbed to find the following statement made by Dr. H. M. Macaulay in his article on "The Staffing of County Hospitals" published in the *Lancet* for Dec. 1 (p. 717):

> "The department of anaesthetics will be staffed, on the same principle, by an experienced senior anaesthetist holding a diploma, a less experienced chief assistant also holding a diploma, as well as resident and house anaesthetists. On the grounds that anaesthetics is a limited speciality, the salary scale is put somewhat lower than that for a general physician or surgeon, and it is recommended that senior anaesthetists should receive £1,000, rising to £1,400, or in cases of exceptional achievement to £1,600. Chief assistants will receive £650, rising to £850, resident anaesthetists £400, and house anaesthetists £250 yearly."

This practice of differentiation between the various specialties is now rather out of date. No such differentiation has been made in the Navy, Army, Air Force, or E.M.S. during the war, and it is presumed that there will be none in the proposed National Health Service. In chap. 4, para. 62, p. 92, the Goodenough Report on Medical Schools deprecates any difference in the rates of pay of various specialists and consultants in regard to their employment as teachers. If this recommendation holds good in the case of teaching, it must surely do so for clinical work, for the same difficulty in getting good men to enter for a poorly paid post will arise. It is common knowledge that the Standing Committee of the three Royal Colleges has established certain criteria for the recognition of consultants. Consultant anaesthetists are proposing to adopt these criteria and will expect in future the same reward as a specialist in any other branch of medicine.

The Council is at a loss to understand what Dr. Macaulay means by a "limited speciality" and would refer him to the annual reports of the Section of Anaesthesiology of the Mayo Clinic in the United States, which show that the limits of the specialty commonly known as "Anaesthetics" in this country are always extending.—We are, etc.,

A. D. MARSTON,
President.
W. ALEXANDER LOW,
Hon. Secretary.

Association of Anaesthetists,
45, Lincoln's Inn Fields, W.C.2.

Buying and Selling Practices

SIR,—This whole question should be reconsidered and discussed from every point of view. There are basic reasons for deprecating the sale of practices altogether. A practitioner presumably charges and obtains a just price for his services to his patients. On giving up practice it is his duty to provide continuity of treatment for his actual and potential patients. Does this justify him in demanding a large capital sum from the successor he has selected, over and above the just price he has received for past services? To many minds this is an unhandsome proceeding which cannot but lead to grave abuse.

Canvassing is forbidden us as members of an honourable profession, though canvassing is universal in the capitalist society in which we practise. To sell to the highest bidder is normal commercial ethics. Is it good enough for our profession? If a practice can be sold the temptation to sell to the highest bidder is inevitable, irrespective of the good of one's patients, which is supposed to determine medical ethics, and inevitable also is the boosting of the proposed buyer, than which there can be no more effective form of canvassing. The effect of selling practices is to make boom periods still more "booming" and to cause "slumps" to "slump" still further. A prospective seller is always tempted to wait for the former and artificially inflate his practice as much as possible while the going is good. The sale of practices encourages the technique and methods of the practitioner who believes and preaches that the best doctor is he who charges the highest fees and makes the most visits. Many a beginner or newcomer finds too late that he has bought the bad-will of patients increasingly resentful, who are only waiting for the seller to go to "make a change," and that he faces a time of slump with a boom debt.

If, however, the whole status of the medical practitioner as hitherto understood in Christendom is to be altered other considerations come in. Hitherto the patient and doctor have both been principals in the business of diagnosis and treatment, and no third person has the right to intervene. But if the doctor is to be a conditioned agent of the politicians and the civil servants, vetting according to the plans of these gentry a conditioned worker, this is so alien a notion to Western civilization and to what the profession has hitherto understood that practitioners may justly press for reasonable compensation from the politicians for loss of income.—I am, etc.,

London, N.16. E. H. STRANGE.

SIR,—According to the latest Ministerial pronouncement the buying and selling of medical practices is to be abolished by legislation. A schedule of the capital values invested in, or represented by, the different practices will be a necessary preliminary to any measure of compensation to individual practitioners. In any such valuation it is to be hoped that consideration will be given to the position of those doctors—notably in London and the East Coast towns—whose practices largely disappeared as a result of war risks and incidental conditions. Their patients migrated, either voluntarily or under official pressure, and went to swell the practices of colleagues in other parts of the country. The doctors found other employment, mostly in one of the Services, and have so far had little or no chance to resuscitate their pre-war practices and re-establish their "capital value." In these cases, at least, it would seem equitable to make a valuation based on the 1939 earnings, as shown by certified accounts or income-tax returns.—I am, etc.,

"THANET."

The Bristol Council for Rehabilitation has appointed the following officers: Chairman, Mr. A. G. Thompson; Vice-Chairman, Mr. F. R. Imison; Joint Hon. Secretaries, Mr. P. Hanks (secretary, Winford Orthopaedic Hospital) and Mr. John Dodd (hon. secretary, Bristol and District Divisional Hospitals Council). Reference was made at a meeting of the committee to the reluctance of disabled people in Bristol and district to register under the Disabled Persons (Employment) Act. The Council hopes that disabled persons (including those who may think their long-standing disabilities preclude any possibility of their getting employment) will realize that it is to their advantage to register under the Act.

Obituary

LEWIS CAMPBELL BRUCE, *M.C.*, M.D., F.R.C.P.Ed.

The death of Lewis Campbell Bruce on Dec. 3 in his 79th year severs almost the last link with the supreme period of Scottish psychiatry in the closing years of the last century and the early ones of this. There were giants in the land in those days, and it is strange to reflect that Bruce was regarded by many of them not only with respect as an original thinker and worker, but also, and even chiefly, as a dangerous innovator and something of a revolutionary.

He qualified at Edinburgh in 1894 and had an Army career as his goal, but had the great misfortune, in those days of few vacancies and severe tests, to fail to gain entrance either to the R.A.M.C. or to the I.M.S. He turned his attention to psychiatry, and joined the staff of Morningside under Sir Thomas Clouston. There he developed that combination of clear scientific thinking with intense energy and enthusiasm which characterized his whole life. In 1899 he was appointed medical superintendent of the 400-bed Perth District Mental Hospital at Murthly in succession to Prof. G. M. Robertson, who had been appointed to Larbert. Six or seven years later he suffered the crowning disappointment of his career when, to the general surprise, Robertson, and not he, was appointed to succeed Clouston at Morningside. As it happened this apparent setback was the proverbial blessing in disguise, for Bruce, with all his brilliancy, would have been miserable in the post. He was rather embittered for a time, and one or two further opportunities of promotion were practically thrown away by him, apparently by his offhand manner, but perhaps because he was already realizing that he was the ideal man for Murthly and Murthly was the ideal place for him. Into that small country hospital beside the River Tay he threw all his abilities and energies, and for 35 years made it a model of efficient and enlightened administration, a place of humane and skilful psychiatric treatment, and a source from which proceeded first-rate scientific work. He established and equipped a small laboratory which was his constant joy and pride. He trained members of his staff to do the work of laboratory technicians, prepare media, look after the animals for experiment, and so forth, and was one of the first medical superintendents, if not indeed the very first, to put out his own original work from the hospital of which he was in charge.

It was Bruce who introduced the thyroid treatment of the insane. He was an enthusiast on vaccine therapy, and one of his chief lines of research was on blood changes in the manic-depressive psychosis—the subject he chose for his Maudsley Lecture in London in 1935. His scientific work never received all the recognition it deserved, partly because of the advances in knowledge and change in outlook during the last twenty years, and partly no doubt because he worked in isolation, and not in association and collaboration with others. But the memorable thing about his work is not its value and results so much as the amazing pertinacity and skill with which it was carried out in a tiny laboratory, often with improvised or home-made instruments and apparatus, without the stimulus of colleagues, and in the teeth of obstruction and misunderstanding from an uninformed hospital committee.

Bruce was a devotee of scientific method and clear thinking, and his other ruling passion was the open air and every form of outdoor life and activity. He had one assistant medical officer, and, as a rule, liked a change every eighteen months or so. Fortunate indeed were the men who had a period at Murthly as their introduction to psychiatry. The first practical result with most of them was the completion of an M.D. thesis, more often than not up to gold medal standard. Bruce was forthright and outspoken to a very great degree. He was often the reverse of tactful, was matter-of-fact and unsentimental; he not merely could not suffer fools gladly, he could not suffer them at all. Doubtless, especially in his earlier days, he antagonized those who did not know him, and very few people whom he disliked remained in ignorance of the fact; but a short acquaintance made it clear that his impulsive ways and his sometimes caustic words were expressions of a loathing of cant or affectation and a flaming scorn of anything mean or insincere. He had no use for "sobstuff" and a bitter contempt for the shirker, but his kindness to anyone who was sick or in trouble and his understanding and toleration of human frailties and lapses were unbounded. His administration was strict, and his discipline may have seemed stern and even harsh at times to outsiders, but few, if any, medical superintendents can have been held in such affection by their medical and nursing staff as he. No one who worked for him could fail to realize that he was a man with whom fair play was a passion, and to whom one could safely confide one's inmost secrets and deepest troubles.

Bruce's mental and physical energy were alike amazing. The day's routine at Murthly, with its altogether delightful mixture of work and play, both at full pressure and express speed, may perhaps seem a little old-fashioned to modern neuropsychiatrists, but it was a uniquely pleasant and beneficial experience to the succession of assistants who enjoyed it year after year, until, as he characteristically remarked, the time came when they became more trouble to train than they were worth, and he carried on the work of the hospital single-handed. After the outbreak of war in 1914 he gave his committee no peace until he obtained their permission to join the Forces. He went to Gallipoli at the age of almost 50, acquitted himself gallantly, and was awarded the Military Cross. On his return he ran Murthly as a war hospital for a year or two, and then settled down again, with characteristic lack of fuss, to civilian life.

Bruce was a born teacher, concentrating on the physical aspect of mental disease. He had no use for psychopathology, nor did it interest him. As a clinician, however, he was in the first rank. He had many friends in the medical faculty of Edinburgh University, and made a point of keeping in touch through them with every development in clinical medicine and biochemistry. Above all he insisted upon the great principle that it is impossible to understand the psychoses, or even to talk sense about the psychoses, unless one has lived among psychotic patients. Slovenly work or muddled thinking he abhorred, and few people would willingly risk his displeasure twice. On the other hand, few indeed of those who ever worked for Bruce left his service without feelings of gratitude and affection, and none without feelings of respect. To have made himself generally recognized during so many years in that small country hospital as one of the keenest scientific minds, and certainly the most vivid personality, in Scottish psychiatry was a supreme achievement. He retired in 1936 and carried on his country pursuits near Lockerbie in Dumfriesshire, where the local people, once they appreciated that here was a man whose knowledge of country life was unsurpassed, made him very welcome. The old impulsiveness and irascibility had become mellowed, but the clear-thinking brain was alert to the very end, and his interest in every psychiatric development was as keen as ever.

H. Y.

G. ARBOUR STEPHENS, M.D.

Dr. George Arbour Stephens of Swansea, who died suddenly on Dec. 1, was of Huguenot descent through his father, was born on the other side of the Loughor, at Carmarthen, in 1870, and went to school there, afterwards going on to University College, Aberystwyth. In 1888 he took the B.Sc. of London University, with honours in zoology, and entered for his medical training at University College Hospital, London, qualifying M.B., B.S. in 1892, with first-class honours in materia medica and honours in medicine. In the following year he took his M.D. Settling in Swansea, he remained there for the whole of his professional life. In later years he specialized as a cardiologist and also in industrial medicine. He was consulting cardiologist to the Welsh National Memorial Association and to Carmarthen County Council and consulting physician to the Cardigan and District Memorial Hospital and to Llandovery and Clydach cottage hospitals. He took an outstanding part in the initiation of infant welfare work in Swansea, was co-founder of the first Mothers and Babies Welfare in Wales, and a pioneer of mothercraft classes for schoolgirls and of the institution of school meals. His position as a surgeon under the Factory Act gave him long experience of some Swansea industries, and he carried out some research in this field. He was a past-president of the Swansea Medical Society.

Arbour Stephens took a considerable part in the public life of his town and of the Principality. For 13 years he was a member of the board of guardians and for some time chairman of the Glamorgan joint poor-law committee for the feeble-minded. For 18 years he was a member of the town council, latterly an alderman, and for 9 years chairman of the education committee. He represented the Swansea municipality on the governing body of the University College; the college had been intended only for science courses, but on his advocacy it was widened to include the full arts faculty. Recently he had advocated a veterinary college for Wales. His principal medical writings were on the prevention and relief of heart diseases and on the heart and spleen in health and disease. He also wrote on archaeology and folklore. He first joined the British Medical Association in 1901. He married in 1922 Mary Williams, D.Litt., professor of modern languages, Swansea University College.

F. H. K. K. writes:

The sudden death of George Arbour Stephens deprives the profession of a dignified, cultured figure whose wide interests covered a very large field not only in his own profession but also in the field of local government and particularly in education. Settling in general practice in Swansea he soon built up a reputation for originality of outlook, and he had no hesitation in discarding any orthodox views if they did not come up to his own high standards of scientific truth. Later he specialized in cardiology and industrial medicine, and the almost total disappearance of cases of lead poisoning among the spelter workers whom he regularly examined and on whose welfare he wisely advised is perhaps the greatest monument to his life's work. He served on the Swansea Board of Guardians for many years and for 18 years served on the Swansea town council, many of which years were spent as chairman of the education committee. He was on the governing body of the University College of Swansea and of the National Library of Wales and also the Welsh National Museum. His ideas were prolific and many of them in advance of his time, and the non-acceptance of some of them left him scornful of his fellows. Nevertheless those who knew him best and those who had received at his hands help, advice, and comfort when in distress will remember him as a dignified, wise, and generous-hearted colleague and a fine useful citizen.

H. M. MORAN, Ch.M., F.R.C.S.Ed., F.R.A.C.S.

Herbert Michael Moran, born of Irish parentage on April 26, 1885, died at Cambridge on Nov. 20. He graduated at Sydney in 1907, and after resident appointments toured Great Britain in 1908 as captain and "guardian angel" of the first visiting Australian rugby football team. When the team returned to Australia "Paddy" Moran remained behind in England and continued his postgraduate studies, taking his F.R.C.S.Ed. He became extremely interested in radium and the development of radium therapy both in England and on the Continent, as well as in America. In order that he might utilize the knowledge and experience he had gained in this field he took back to Sydney with him several thousand pounds' worth of the (then) new radium needles. Until his retirement in 1935 he held the appointment of cancer specialist at Prince Henry's Hospital, consultant at the Royal Prince Alfred and the North Shore Hospitals, surgeon at the St. Vincent's and Lewisham Hospital; and lecturer in radiotherapy at Sydney University. During 1934 he gave a series of lectures in the treatment of cancer by radium to the medical profession in New Zealand, at the instance of the New Zealand branch of the British Empire Cancer Campaign. In 1935, although a surgeon, he was president of the Section of Radiology and Radiotherapeutics of the B.M.A. Annual Meeting held at Melbourne.

During the first world war he served in the R.A.M.C., and rejoined it in 1939, retiring as lieut.-colonel in 1945. His deep interest in human nature, together with his shrewd sound judgment, amply fitted him for the position of president of the Eastern Command standing medical boards, which he held for the last years of his life. His interests were not only in medicine and sport but also in foreign languages and literature, and his achievements in these fields were notable. Having initiated the teaching of Italian language and literature he became in 1934 acting president of the Foreign Language Association, Sydney; a member of the French society, "Amitiés"; and a life member of the Dante Alighieri Society. The Paul Bosell medal for Italian language and literature was awarded him, and his work in encouraging the study of languages was recognized by the conferment of Knight Commander of the Order of the Crown of Italy and Chevalier in the Order of St. Maurice and St. Lazarus. In 1934 he founded the Sydney branch of the Guild of St. Luke and St. Damian, Sydney. His autobiography, *Viewless Winds*, was published in 1939; *Beyond the Hills Lies China*, a narrative, in 1945. The continuation of his autobiography, *In My Fashion*, will be published in 1946. He was a life member of the New South Wales Rugby Union as well as Australian representative on the English Rugby Council. This interest in sport characterized his whole life. His dash and verve and leadership, coupled with his scholastic ability, endeared him to many. He died as he had lived, a sportsman to the end.

C. F. E.

MARGARET BALFOUR, C.B.E., M.D.

Miss C. L. Houlton, M.D., F.R.C.O.G., Secretary, Medical Missions, S.P.G., writes:

The news of the death of Dr. Margaret Balfour will be received with great regret by all medical women in this country and in India. Dr. Balfour had a most distinguished and varied career in India. She will long be remembered for the great service she gave to Indian women in the provision of medical relief, especially to those prevented by purdah restrictions from being attended by medical men.

Dr. Balfour first went to India in 1892, and until her retirement in 1924 devoted herself unsparingly in the advancement of medical services for the women and children of India. She was intensely interested in all problems relating to maternal and child welfare, and especially in research connected with anaemias of pregnancy and osteomalacia. Her stimulating personality enabled her to arouse enthusiasm in all those with whom she worked. Nothing daunted her, nothing discouraged her, and she never lost her keenness. Dr. Balfour's outstanding achievements were connected with the Countess of Dufferin's Fund. This Fund was formed in 1885 by Lady Dufferin to bring medical aid by women to the women of India, and undoubtedly carried out a great piece of humanitarian work; but after Lady Dufferin's departure from India the activities of the association gradually decreased and its reputation fell. The position of medical women serving in the association was most unsatisfactory and caused great discontent in the profession. Representations by medical women were made to the Government of India and to the Secretary of State for India which finally resulted in the foundation of the Women's Indian Medical Service in 1914. After a delay of two years Dr. Balfour was appointed joint secretary of the Countess of Dufferin's Fund and chief medical officer of the Women's Medical Service. The duties of the secretary included administration of the Women's Medical Service—that is, the inspection of the personnel, the selection of applicants in India, the arrangements of appointments, transfers, etc. They included also the secretaryship of the Funds of which the Viceroy's wife was president—the Countess of Dufferin's Fund, of which the income was spent in grants to hospitals, and the Victoria Memorial Scholarship Fund, used for assisting in the training of indigenous dias; and later the Lady Chelmsford All-India League for Maternity and Child Welfare was added to the other duties. New lines of activity suited to Indian conditions were to be thought out and organized in the Dufferin office, and Dr. Balfour's initiative and energy were responsible for working out schemes on preventive medicine, especially relating to the problem of childbirth and child welfare. She was largely responsible for the initiation of the "Health School" in Delhi for the training of health visitors and maternity supervisors, and also for the first Maternity and Child Welfare Exhibition held in Delhi in 1920. The organizing work of the exhibition was done in the Dufferin office, and involved an immense amount of labour on the part of Dr. Balfour. Looking back it is clear the exhibition was a remarkable effort and one which had an immense effect in stimulating people to take up child welfare work in India.

Dr. **GEORGE A. MAXWELL HENDRY**, who has died at the early age of 33, studied medicine at Aberdeen University. As a student he suffered a prolonged interruption of his work due to a serious illness. He faced this setback bravely, however, and graduated M.B., Ch.B. in 1941, having reason to hope that his recovery might be permanent. After qualifying he entered general practice as an assistant in Aberdeen and latterly in Beauly. He became a member of the B.M.A. Early this year, wishing to qualify for a higher degree, he took up work at the Southern General Hospital, Edinburgh. Those who knew Hendry most intimately, writes a colleague, speak of him as a tireless worker. Clinical findings had to be checked over and over again before Hendry was satisfied, and he would spend hours on a difficult or puzzling case. Essentially a worrier, he was ever solicitous of his patients' well-being, while many a time his Scottish humour helped to make the rough places smooth. Perhaps it was because he had faced trouble in his own life that he was enabled to be extraordinarily gentle and kind in the presence of sickness or bereavement. In hospital Hendry was never far away from the bedside, or the microscope, or the laboratory, and this capacity for hard work and thoroughness spread infectiously to the medical students under his wing. His case notes remain as an example of all that case notes should be—concise, exhaustive, accurate. It was a shock to his friends when a recrudescence of his former illness occurred. He had to face the dreary prospect of prolonged invalidism; and for a time it seemed that he might do well. The suddenness of his final passing on Nov. 29 was as unexpected as it was tragic. Dr. Hendry was the only surviving son of Dr. and Mrs. G. F. J. Hendry of Voe, Shetland. Prof. L. J. Davis sends the following appreciation: Although G. A. M. Hendry had been qualified longer than most hospital residents on first appointment, and had been away from hospital work for some years, he was one of the most satisfactory house-physicians it has been my good fortune to encounter. His enthusiasm for his work was unbounded and his conscientiousness outstanding. Although he had acquired a sound knowledge of medicine, his approach to clinical problems was always attended by a thoughtful humility and a desire to learn all that careful observation and untiring inquiry could teach. He had, furthermore, a very pleasant personality, being popular alike with patients, students, and staff. His tragic death at the early age of 33 removes a very promising member of the profession, and one of a type that can ill be spared.

The death of Dr. **ROBERT GORDON** at the age of 82 occurred on Nov. 13 at his residence at Beaconsfield, Bucks, where he had lived in retirement for twenty years. Graduating M.B., C.M. at Edinburgh in 1885, he proceeded to the M.D. degree in 1899, and thereafter practised in Sheffield until his retirement in 1925. He was representative of the Sheffield Division of the B.M.A. from 1909 to 1913, a member of the Division executive committee from 1904 to 1914, and vice-president of the Section of Diseases of Children on the occasion of the Association's Annual Meeting at Sheffield in 1908. During the war of 1914–18 he was appointed visiting physician to the Wharncliffe War Hospital, and afterwards became one of the examining medical officers to the Ministry of Pensions as a neurologist. Dr. Gordon enjoyed the affectionate regard of many friends; and at Beaconsfield after his retirement he soon became an active member of the community. He was a member of the local urban district council for some years, and his sound judgment and kindly interest in the welfare of others continued until his death. He will be greatly missed by all who were privileged to know him.

JAMES CHARLES BUCKLEY, M.D., died at Southfields, Bramcote, Notts, on Nov. 18 in his 77th year. Until four days previously he had been in active practice, and one remembers him once saying he hoped he would meet his end just in this fashion. After graduating at Manchester University and holding various house appointments, Buckley engaged in general practice in Nottingham. His interests were attracted to venereology, and by 1914 this specialty made up about half of his practice. When in the R.A.M.C. his work was confined to venereology, and in 1917 he was released for the purpose of starting the Nottingham Clinic. Under his direction the clinic was organized and expanded until it became one of the most important of provincial treatment centres. He was also in charge of clinics at Mansfield and (for a time) at Newark, and carried on a large private practice. Although he retired from the Nottingham Clinic in 1938 his activities were not greatly reduced, and he actually opened a new centre recently at Worksop. Those who have worked with Buckley will always remember his great store of energy and excellent organizing abilities. Good-tempered and kindly, he did not suffer fools gladly, and this combination enabled him to run a large clinic with the minimum of friction. He played an important part in the growth of venereology as a specialty, and although he did not write many articles his influence was felt in the committee room as a sound and practical planner who was really able to make things work. In his spare time Buckley bred racing pigeons, and secured many successes, notably in long-distance races from San Sebastian. During the last two wars the pigeons were used for military purposes. He was president of the National Flying Club for many years. He is survived by a son and daughter.—A. D. F.

Dr. **THOMAS AUBREY**, born in 1876, died suddenly and peacefully on Nov. 23 of heart failure. He had an attack of coronary thrombosis three years ago; after a few months he resumed his full activities in a very busy practice. The eldest son of Thomas Aubrey, F.R.C.V.S., of Bath, he was educated at Berkhamsted, Bristol University, where he had a brilliant career as a medical student, and St. Bartholomew's; he obtained the Conjoint diplomas in 1899 and the M.B.Lond. in 1902. He practised at Isleham, Cambs, and Bridgwater before settling at Bitton, Glos, in 1905. He was district medical officer for Bitton, Kelston, and North Stoke, and medical officer to Mangotsfield and Warmley Joint Isolation Hospital, and for many years M.O.H., Warmley Rural District Council. He had also been surgeon to the Post Office, casualty officer, Bristol General Hospital, clinical assistant, Brompton Chest Hospital, and junior clinical assistant, Golden Square Throat Hospital. He married in 1900 Mia Isabel Castle, by whom he had one daughter, who died in the influenza epidemic of 1918, and one son, acting wing commander, medical, who lost his life on active service in North Africa in 1943. Mr. Beardmore writes: "It is almost impossible to overestimate the esteem and affection in which Dr. Aubrey was held by the people of Bitton and district, the scene of his labours for the last forty years. He was so much more than their doctor—he was their counsellor and intimate personal friend, and on the autumn day on which he was laid to rest the social and industrial life of the district was stilled, the church was full, the path to the grave was lined, and in the village the children from the school and the workmen from the mill stood with bare heads to pay their silent homage to one of the ablest and best-loved men of his generation and station." Dr. D. I. Jones writes: "His was a dynamic personality. An intensive application to practical work every minute of the day and every day of the week, up to his last living day, did not prevent his being up to date in all details of modern knowledge and technique, and *au fait* with affairs, local and general, of everyday life. His practical knowledge of illness, of its treatment, and of folk great and small with whom he dealt daily, was phenomenal."

Dr. **Ernest William Shaw Hughes** died in retirement at his home in Pinner, Middlesex, on Nov. 23. He was born in 1870, eldest son of the Rev. T. A. A. Hughes, Vicar of Shelf, near Halifax, and was educated at Bradford Grammar School and the Leeds Medical School. After qualifying M.R.C.S., L.R.C.P. in 1893 he was for a short time assistant to Dr. Hector at Drighlington, near Leeds, and then set up in practice in 1896 at Lee Mount, Halifax, and continued there until he retired in 1929. Dr. Hughes was a very active member of the local Division of the B.M.A., which he joined in 1901, and held office as chairman and secretary on several occasions. He was also for many years a member of the Halifax Panel Committee. A pioneer motorist, he used a motor cycle in his practice before the end of the last century, and was a founder-member of the Halifax Automobile Club. During the war of 1914–18 he held a temporary commission for a year in the R.A.M.C. and saw service in Malta and in a hospital ship serving the Salonika front. He died after a short illness, and leaves a widow and one son, Dr. F. L. A. Hughes, who is in practice at Malton, Yorkshire.

Dr. **Ernest Alsager Parsons**, who died in Birmingham on Nov. 23, aged 77, was the third son of C. W. Parsons, of Austrey, Warwickshire. Educated at Appleby Magna Grammar School, and apprenticed to a Coventry pharmacist, he later took up an appointment in Rome. Returning to England in 1893, he studied medicine at Mason's College, Birmingham, and Westminster Hospital, and on qualifying M.R.C.S., L.R.C.P. in 1899 entered the service of the Telegraph Construction and Maintenance Company, and served as medical officer on a ship laying cable to St. Helena. He offered his services in the South African War, and joined Sir Frederick Carrington's Rhodesia Field Force. After the war he became senior medical officer to the Beira and Mashonaland Railway Company, an appointment he held until 1907. In 1908 he was employed as one of the medical officers on Sir John Aird's works in connexion with the Assuan Dam extension, in which capacity his command of the Italian language was valuable on account of the large amount of Italian labour engaged. Unfortunately his health broke down and he had to return to this country. On his recovery he joined the staff of Queen's Hospital, Birmingham, eventually becoming the senior resident medical officer. After the 1914–18 war he served as a member of the local Pensions Board. For the last twenty years he had been in private practice in Birmingham.

The death of Dr. **Thomas William Naylor Barlow**, O.B.E., of Wallasey, at the age of 77, deprives his profession of a man with a long and honourable record. He was M.R.C.S., L.R.C.P., D.P.H. of Cambridge, F.R.S. of Edinburgh, and a barrister-at-law. He retired from his post as medical officer of health at Wallasey in March, 1934. He was president of the Society of Medical Officers of Health 1923–4, and was for many years a very active and popular member of that society. He was a member of the Public Health Committee, and several subcommittees, of the B.M.A. from 1923 to 1931. He was a member of the Committee on Medical Aspects of Abortion 1934–6, and represented his Division at the A.R.M. in 1926 and in 1939. He was secretary of the Section of State Medicine and Industrial Diseases at the Annual Meeting at Liverpool in 1912, and vice-president of the Section of Public Medicine at Bath in 1925. In his later years he suffered greatly from rheumatoid arthritis and was thus prevented from taking an active part in medical affairs. Though unknown to many of the present generation, he will be well remembered by his contemporaries as an able medical officer of health, a genial companion, and as a man always willing and able to co-operate with his fellows in other branches of the profession.

The following appreciation of the late Dr. **Henry Ernest Rutherford**, of Larne, Co. Antrim, who died on Nov. 30, has been received from a colleague: By Dr. Rutherford's death Larne and district have lost an outstanding personality. One had only to know his qualifications to appreciate the fact that he was a man of many parts. As a graduate of arts, law, and medicine, he held a unique position among the medical men of Ulster. His outstanding characteristic was the keen interest he took in the welfare of his fellow men, an interest which he maintained until the end. A cultured man and a great reader, he had a sense of humour which made him take a kindly view of the failings of humanity.

The Services

Col. A. H. Harty, C.I.E., V.H.S., I.M.S., has been appointed Honorary Physician to the King in succession to Major-Gen. W. C. Paton, C.I.E., M.C., I.M.S.(ret.).

The following appointments, awards, and mentions in dispatches have been announced for distinguished service during the war in Europe:

C.B.E. (Military Division).—Surg. Capt. J. F. Ainley, R.N. (ret.).

O.B.E. (Military Division).—Surg. Cmdr. J. V. Dockray, R.N.V.R. (ret.).

D.S.C.—Temp. Surg. Lieuts. P. M. Kerr and H. R. Shepherd, R.N.V.R.

Mentioned in Dispatches.—Acting Surg. Cmdr. C. Ommanney-Davis, R.N. (ret.); Temp. Acting Surg. Lieut.-Cmdrs. H. O. Paton, J. F. Ryan, and J. K. G. Way, and Temp. Surg. Lieuts. G. A. Findlay and G. K. H. Hodgkin, R.N.V.R.

CASUALTIES IN THE MEDICAL SERVICES

Died.—Col. Sidney John Liddon Lindeman, O.B.E., M.C., R.A.M.C.

Previously reported prisoner of war, now believed to have been lost in Japanese transport in Oct., 1942.—Capt. Bernard Henry Mooring-Aldridge, R.A.M.C.

Universities and Colleges

UNIVERSITY OF CAMBRIDGE

V. B. Wigglesworth, M.D., F.R.S., of Gonville and Caius College, has been appointed Reader in Entomology. Dr. Wigglesworth is at present Reader in Medical Entomology at the London School of Hygiene and Tropical Medicine, and Director of the Agricultural Research Council Unit on Insect Physiology.

ROYAL COLLEGE OF PHYSICIANS OF EDINBURGH

At the annual meeting of the College, held on Dec. 6, Prof. David Murray Lyon was elected President, and Dr. W. D. D. Small, Prof. L. S. P. Davidson, Drs. J. D. S. Cameron, H. L. Wallace, and I. G. W. Hill, and Prof. D. K. Henderson were elected to form the Council for the ensuing year. Dr. Small was nominated Vice-President.

ROYAL FACULTY OF PHYSICIANS AND SURGEONS OF GLASGOW

Dr. Robert A. McCance, F.R.C.P., will deliver the Dr. James Finlayson Memorial Lecture in the hall of the Royal Faculty of Physicians and Surgeons, 242, St. Vincent Street, Glasgow, on Wednesday, Jan. 9, at 4 p.m. The title of the lecture is "Bread."

Medical News

University College, Southampton, has been holding this week, in conjunction with the British Council, a leave course on "Britain To-day and To-morrow," for members of the Dominions, United States, and Polish Forces, at South Hill, Gleneyre Road, Bassett, Southampton. To-day (Friday, Dec. 21), at 11.45 a.m., Dr. W. P. Cargill lectures on "The Health of Britain."

A general course for demobilized general practitioners has been arranged to begin on Monday, Dec. 31, at Bristol University. It will last a fortnight. The detailed programme has not yet been drawn up, but the course will be essentially clinical. Particular emphasis will be laid on paediatrics and maternity. Other subjects to be included are mental deficiency, public health with fevers, and pulmonary diseases, including tuberculosis. Accommodation will be provided at a University Hall of Residence (Wills' Hall) at a charge of 15s. per day plus 10% for gratuities.

The French Academy of Medicine has elected Sir Alexander Fleming an Associate Member in recognition of his services to medicine by the discovery of penicillin. He shared the honour of election with, among others, Sir Henry Dale, Prof. E. D. Adrian, and Prof. C. H. Best (Toronto); and Sir Wilson Jameson has been elected a Foreign Correspondent of the Academy.

Dr. W. S. C. Copeman has been elected chairman of the Council of the Chartered Society of Physiotherapy in succession to Sir Herbert L. Eason, who has resigned.

As the result of recommendations made by a joint committee of the British Institute of Radiology and the Faculty of Radiologists, the Faculty is setting up an Information Bureau at 45, Lincoln's Inn Fields, London, W.C.2 (Chancery 6965) to assist officers who have served as radiologists in H.M. Forces in obtaining information regarding further training and appointments vacant. The Faculty therefore invites inquiries from such radiologists and is prepared to receive particulars from hospitals requiring radiological staff.

The Ministry of Health states that it has now been agreed by the Service Departments that they will accept liability for the cost of sanatorium treatment of members of the Forces, for the period of such treatment preceding the date of discharge from the Forces, on the same basis as applies between a sanatorium authority and the Ministry of Pensions with regard to the cost of treatment after discharge.

Dr. Robert Noel McKinstry, Medical Officer of Health, Jersey, and Dr. Angelo Nelson Symons, Health Officer, States of Guernsey, have been appointed O.B.E. (Civil Division) for services rendered during the enemy occupation of the Channel Islands.

Dr. Colin Fraser Brockington, at present county medical officer of health for Warwickshire, has been appointed county medical officer for the West Riding of Yorkshire.

Dr. Robert Courrier, professor at the Collège de France and member of the Académie de Médecine, has been elected a member of the Académie des Sciences.

Lord Nuffield, already a munificent benefactor of Worcester College, Oxford, has presented a further sum of £10,000 for the endowment of scholarships for medical students.

EPIDEMIOLOGICAL NOTES

Discussion of Table

In *England and Wales* there was a rise in the incidence of infectious diseases. The largest increases were acute pneumonia 167, whooping-cough 152, measles 48, diphtheria 22; while the only fall was scarlet fever 32.

The only local rise of any size in the incidence of acute pneumonia was Yorks West Riding 76; slightly more than half the total cases notified in this county were recorded in Sheffield C.B. The largest rises in diphtheria were Suffolk 13, Durham 16, Yorks West Riding 12, Essex 11.

The whooping-cough increase was fairly general, and the only rise of note was Essex 31. The increase in measles was contributed by only a few counties; the largest rises were Norfolk 37, and Lancashire 24.

A fresh outbreak of dysentery was reported from Berkshire, Abingdon R.D. 22 cases. The other large returns were Lancashire 40, Surrey 34, Essex 24, London 21, Gloucestershire 19, Glamorganshire 14.

In *Scotland* infectious diseases were more prevalent during the week. The rises included acute primary pneumonia 57, measles 28, scarlet fever 30, dysentery 18, diphtheria 15. The largest rise in diphtheria was that for the city of Glasgow 26. The chief centres of dysentery were Glasgow 26, Renfrew County 16, and Edinburgh 12.

In *Eire* the outbreak of measles in Dublin C.B. showed a further increase; 160 cases were notified during the week. There were 48 cases of diarrhoea and enteritis notified, this disease having been at a practically constant level during the past five weeks.

In *Northern Ireland* a decrease of 11 in the total for scarlet fever was the only change of note in the trends of infectious diseases.

The Health of Bengal, 1941

The birth rate during the year was 31.9 per thousand, and was 5.3% below the rate for 1940. The death rate was 23.7 per thousand, and was 6.6% higher than that of the previous year. The simultaneous deterioration of birth and death rates is a rare event; the last two occasions were 1918 and 1938. Excluding "other classes" the Muslims had the highest birth rate (32.1) and the highest death rate (24.6). Infant mortality was 156 per thousand live births, compared with 159 in the previous year. A general increase was recorded in epidemic diseases. The chief causes of death were malaria 388,381 deaths (32.8% of the total deaths recorded), cholera 61,879, smallpox 13,250, kara-azar 16,349, and dysentery and diarrhoea 51,529.

Week Ending December 8

The notifications of infectious diseases in England and Wales during the week included: scarlet fever 1,779, whooping-cough 1,225, diphtheria 574, measles 611, acute pneumonia 744, cerebrospinal fever 41, acute poliomyelitis 28, dysentery 242, and typhoid 5.

No. 48

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended Dec. 1.

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for: (a) England and Wales (London included). (b) London (administrative county). (c) Scotland. (d) Eire. (e) Northern Ireland.

Figures of Births and Deaths, and of Deaths recorded under each infectious disease, are for: (a) The 126 great towns in England and Wales (including London). (b) London (administrative county). (c) The 16 principal towns in Scotland. (d) The 13 principal towns in Eire. (e) The 10 principal towns in Northern Ireland.

A dash — denotes no cases; a blank space denotes disease not notifiable or no return available.

Disease	1945					1944 (Corresponding Week)

Stillbirths	209	20	29			220	18	29		
Rate per 1,000 total births (including stillborn)			35					33		

* Measles and whooping-cough are not notifiable in Scotland, and the returns are therefore an approximation only.

† Includes primary form for England and Wales, London (administrative county), and Northern Ireland.

‡ Includes puerperal fever for England and Wales and Eire.

§ Owing to movements of population, birth and death rates for Northern Ireland are still not available.

Letters, Notes, and Answers

All communications with regard to editorial business should be addressed to THE EDITOR, BRITISH MEDICAL JOURNAL, B.M.A. HOUSE, TAVISTOCK SQUARE, LONDON, W.C.1. TELEPHONE: EUSTON 2111. TELEGRAMS: *Aitiology Westcent, London.* ORIGINAL ARTICLES AND LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated.

Authors desiring REPRINTS should communicate with the Publishing Manager, B.M.A. House, Tavistock Square, W.C.1, on receipt of proofs. Authors over-seas should indicate on MSS. if reprints are required, as proofs are not sent abroad.

ADVERTISEMENTS should be addressed to the Advertisement Manager, B.M.A. House, Tavistock Square, London, W.C.1 (hours 9 a.m. to 5 p.m.). TELEPHONE: EUSTON 2111. TELEGRAMS: *Articulate Westcent, London.*

MEMBERS' SUBSCRIPTIONS should be sent to the SECRETARY of the Association. TELEPHONE: EUSTON 2111. TELEGRAMS: *Medisecra Westcent, London.*

ANY QUESTIONS?

Nodule at Site of A.P.T. Injection

Q.—*What is the cause of the small nodule which often appears at the site of A.P.T. injection? Has its size any relation to the degree of immunity that may be expected?*

A.—The difference between alum-precipitated and other toxoids is that alum precipitation renders toxoid much more insoluble. It is therefore more slowly absorbed and hence can be given in more concentrated form; this is the reason for its greater efficacy. The nodule referred to is a depot of the material itself, with a surrounding area of leucocytic infiltration. Neither the intensity of the initial inflammatory reaction nor the size of the nodule persisting thereafter bears any relation to the degree of immunity produced. Sensitiveness to this product, which determines the degree of local reaction produced by it, has no connexion whatever with immunity. This reaction is usually slight in children, who tend to be highly susceptible, and often much more severe in adults, who in general have a higher degree of partial immunity.

Treatment of Syphilis

Q.—*A man contracted syphilis at the age of 16, was treated, and thought himself cured. Symptoms recurred when he was 22, and he had "mercurial treatment." Now at 47 he has an ulcer on the border of the tongue, with a small yellow slough in the centre. A specialist agrees that it does not look carcinomatous, but will take a section for microscopical examination. The Wassermann is positive (1 in 4 dilution). I have prescribed pot. iod. 20 grains daily (and will increase to 40 grains in three weeks), and an injection of oil-soluble bismuth weekly. Would metallic bismuth suspended in glucose be better? Would a trivalent intravenous arsenic injection make his liver a mass of fibrous tissue?*

A.—It appears probable that the lesion is a gumma, but a biopsy should be carried out to exclude malignant disease. Oil-soluble bismuth is normally used when a rapid therapeutic effect is desired, a suspension of the metal when a slow prolonged effect is the object; in this case the latter preparation seems preferable. The suggestion that "a trivalent intravenous arsenic injection" might "make his liver a mass of fibrous tissue" is absurd. This would only happen if he developed (infectious) hepatitis, which can almost certainly be avoided by employing a strictly aseptic technique. At first neoarsphenamine should be given intravenously, in weekly doses, of 0.6 g., concurrently with the bismuth, a careful watch being kept for toxic effects; later, bismuth may be used alone. If the ulcer proves malignant, antisyphilitic treatment should be carried out as soon as the patient has recovered from any operation; it would be as well to have the cerebrospinal fluid examined, and if asymptomatic neurosyphilis is present treatment should be modified accordingly.

Weight of Enlarged Prostates

Q.—*What is the average weight of prostates removed for adenomatous enlargement? What is the weight of the heaviest one that has been removed?*

A.—The average weight is 1½ to 3 oz., and 6 oz. is a large one. So far as the writer knows, 18½ oz. is the heaviest ever removed.

Tuberculin-tested Milk

Q.—*If the producer of tuberculin-tested milk bottles it and delivers it himself, is he free from the obligation to state on the bottle or the seal that it is tuberculin-tested milk?*

A.—If a vendor of tuberculin-tested milk sells it specifically under this designation it must be labelled according to the Order, whether he produces the milk himself or not. If he bottles it on the farm he is entitled to add the term "(Certified)" to the designation "Tuberculin-tested Milk." There is, however, no obligation on any vendor to label milk as tuberculin-tested merely because it is from a tuberculin-tested herd and because he is licensed to sell milk under the designation, so long as he sells it as milk without any designation and demands no extra price for it.

Sudeck's Arthritis

Q.—*What is the aetiology, particularly in relation to injury, of Sudeck's arthritis or atrophy of hand and other bones?*

A.—It was in 1900 (*Arch. klin. Chir.*, **62**, 147) that Sudeck published his original paper on the dystrophy of bones of the extremities which might follow injury; since then there have been many studies of the subject, including another excellent article by Sudeck himself in 1938 in the same journal (*Arch. klin. Chir.*, **191**, 710).

The condition usually follows minor injuries or sprains. The symptoms are persistent burning pain, oedema of the subcutaneous and periarticular tissues, and redness of the skin, followed later by shrinking of the oedematous parts, stiffness of the joints, and atrophy of the bones of the affected extremity. The pathology is not fully understood. The condition has been termed acute reflex bone atrophy, on the assumption that the vasodilatation which is responsible for the bone absorption and atrophy is due to a nervous reflex originating at the site of injury. This view would appear to be confirmed by the testimony of many who have shown that the pain may be abolished, or at least greatly diminished, and the later crippling effects largely prevented, by section of the sympathetic supply above the site of the lesion. There are difficulties in the way of accepting this view. Stimulation of the proximal end of a peripheral nerve usually leads to vasoconstriction, and section of the sympathetic should cause vasodilatation—a condition which already exists in Sudeck's disease and in the somewhat similar condition causalgia. Lewis showed that in causalgia the redness, heat, and tenderness were due to the local effect of substances liberated peripherally, and some observers consider that a similar mechanism may be responsible for the vasodilatation in Sudeck's atrophy. The matter is still in need of further research to determine the correct pathology.

It is important to make an early diagnosis if disability is to be prevented. When there continues to be complaint of persistent burning pain and one observes periarticular oedema in a case of sprain, contusion, or wound, which is not septic and has been properly immobilized, one must always bear in mind the possibility of reflex bone atrophy. The pain may be relieved or abolished, and the possibility of bone absorption and atrophy diminished, by section of the sympathetic above the lesion, by means of local infiltration, paravertebral injection, periarterial sympathectomy, or by ganglionectomy.

Soapless Shampoos

Q.—*Many of my patients wash their hair with soapless shampoos. What is soapless shampoo, and is it harmless?*

A.—Soapless shampoos consist of sulphonated oils and sulphonated higher fatty alcohols. They are harmless on a healthy scalp.

Signs of Virginity

Q.—*What are the signs of virginity in a girl under 15 years? What would be the changes after one, and after several, connexions?*

A.—The signs of virginity in a girl under 15 are an intact hymen and apposition of the labia majora. Although an intact hymen is the main indication of virginity it is not proof of it, because occasionally intercourse can take place without rupture. Proof of intercourse rests on the demonstration of spermatozoa in the vagina, usually accompanied in first intercourse by rupture of the hymen. When the hymenal tear has healed no just opinion can be given as to the number of times connexion has occurred, but in the woman habituated to intercourse over a number of years the labia majora will not remain in apposition and the introitus tends to gape. One is not justified in certifying that intercourse has taken place from the observation of a healed rupture of the hymen alone.

Thought and the Electro-encephalogram

Q.—*In a recent Brains Trust Dr. Julian Huxley implied that the electro-encephalogram provided evidence that thinking was accompanied by a mechanical process in the nervous system. Is this so?*

A.—No, it is not, but if "physical" were substituted for "mechanical" the statement might possibly be defended. No one would doubt that thought is associated with electrical changes in the brain, but there are no "mechanical" concomitants of these changes. Even so, the electro-encephalogram gives little or no evidence about the processes involved in thought. There is the negative observation that many of the electrical oscillations observed in the E.E.G. cease during periods of attention or thought, but this is probably unrelated to the electrical activity upon which the transmission of impulses subserving thought depend. There are also the abnormal rhythms which are associated with abnormal thought and behaviour, as in epileptics and psychopaths, but here again no evidence is provided upon the nature of thinking. The E.E.G., in fact, gives a record of a crude end-result of the living activity of brain cells, but there is no evidence that the changes in any way reflect brain function.

The "Highly Strung" Child

Q.—*How should one manage and treat a "highly strung" 4-year-old?*

A.—At 4 years old troubles of many kinds are normal concomitants of development. The anxiety of good parents, who blame themselves when their children are difficult, often raises tension in the home to a point unbearable to both sides, and a statement by the doctor that at this age emotional upsets are as much to be expected as was teething at an earlier stage will often bring much relief to father and mother, and through them to the children. Freedom from anxiety in the adults, insight into the causes of strain in the child, together with love, toleration, and supporting control, form the basis of good home management. At the age of 4 a child is working out his relationships with parents, siblings, and outsiders; he is experiencing a healthy rivalry with the adult world, while increasingly conscious and impatient of his own limitations. He is greedy both for power and for protecting love, and is haunted by fantasies in which through gaining power he becomes dangerous and so provokes anger in the parents whose love is vital to him. Such a "normal" conflict is painful, especially if exacerbated by such traumata as illness, separation from the mother, etc. Many naughtinesses, feeding difficulties, tempers, and disorders of habit may represent the question, "Do you love me even if I am horrid?" while the harsh self-criticism, felt though not verbally expressible in early childhood, makes it hard to accept reassurance till many times repeated in word and act. A clever mother can do much by encouraging independence combined with protectiveness towards herself, and by tranquilly accepting boasts. The small boy in *When We were Very Young* who warned his mother, "You must never go down to the end of the town unless you go down with ME," was solving his problem in this way, and asking her admiration of him as protective male. At this age, when boys become defiantly masculine, fathers can help to allay conflicts by inviting partnership in various activities, as can mothers with little girls, whose developing maternal instincts and love towards the father will otherwise arouse the anxiety associated with rivalry and guilt.

Play is an important factor in mental health. Large toys, such as wooden engines and trucks, a set of bricks, sand and water, and other material for imaginative play are valuable, as are simple constructional toys that develop skills and provide satisfaction through achievement. A highly strung hyperactive child is often afraid of his own aggressive impulses, and so finds comfort in external control of a gentle kind. If he is unhappy, showing physical symptoms that appear psychogenic, or if his difficulties are inappropriate to his developmental stage, it is likely that he needs child-guidance treatment. As a first-aid measure, however, it is sometimes worth trying phenobarbitone, gr. 1/8 to 1/2, morning and evening, which may provide sufficient mental relief to enable a child to work through his problems with the aid of improved management at home.

Symptomatic Treatment of Cough

Q.—*What is the symptomatic treatment of cough in cases of pneumonia?*

A.—Cough in pneumonia requires treatment: (1) if the cough is unproductive and interfering with the patient's comfort or rest; (2) when the cough is productive but the sputum is so viscid that the cough exhausts the patient without adequate result.

When the cough is not productive it is useless and should be damped down. The milder degrees are best dealt with by the use of a codeine linctus containing, e.g., codeine phosphate (gr. 1/16 to gr. 1/8), every four hours. For the more severe types linctus heroin. (gr. 1/32 to gr. 1/8) should be used sufficiently often to produce the required result. Often the unproductive cough requires treatment not so much in itself as because of the pain it causes; in these cases the pain rather than the cough should be treated.

When the cough is productive warm alkaline draughts (sod. chlor. and sod. bicarb. āā gr. 15 in 2 oz. of warm water, four-hourly) are most useful. With these a mixture of old matured tinct. camph. co. and oxymel of squill āā gr. 30 should be given. This has been proved to have an expectorant action as well as making the cough less frequent. In some of these cases there is an element of spasm, and small doses of pot. iod. and stramonium are of value.

Diet in Chronic Interstitial Nephritis

Q.—*Please describe the modern dietetic treatment for chronic interstitial nephritis, with raised blood pressure and oedema of the eyelids in the morning.*

A.—The chief aim of modern dietetic treatment is to maintain nutrition without making unnecessary demands on kidneys which are diminished in function as well as structure. The principles of the diet are as follows: (1) Abundant fluids to satisfy thirst and to maintain the beneficial polyuria. (2) Enough food to provide an energy value of 2,000 calories, unless obesity indicates a reducing diet. (3) Enough protein to prevent depletion of body proteins. About 70 g. daily should be enough unless there is heavy albuminuria, when protein intake should be increased. (4) Enough milk, fruit, and vegetables, which produce an alkaline ash, to oppose the common retention of predominantly acid protein end-products. When obtainable, two pints of milk daily form a good foundation for this diet, providing 40 g. of protein yet contributing to the alkaline ash balance. Details of the reaction of ashed food products are given in M.R.C. Special Report Series No. 235, 1940, by R. A. McCance and E. M. Widdowson. (5) Salt according to the patient's taste unless there is good reason to differ from him. If there is a tendency for oedema to occur, as in this case, surplus salt should be avoided and no salt added to the food apart from the normal amount used in cooking. Salt depletion is a grave danger in chronic interstitial nephritis because it may promote dehydration and unmask uraemia.

Tuberculosis and Diabetes

Q.—*Is there any evidence that a high blood sugar is harmful in the absence of ketosis in pulmonary tuberculosis complicating diabetes mellitus? Many young diabetics remain well on an uncontrolled diet with insulin; the urine is sugar-free in the mornings but hyperglycaemia and glycosuria occur after meals without ketonuria, as judged by the sensitive nitroprusside test; symptoms of diabetes are absent and weight is maintained. Is the non-restricted diet with insulin, allowing hyperglycaemia and glycosuria without ketonuria, permissible in the diabetic case of pulmonary tuberculosis?*

A.—This question raises two problems:

(1) Does a high blood sugar render patients more liable to develop other diseases? It is believed that this is the case, but the proof is not conclusive. Diabetes is always considered one of the causes of sciatica, but sciatica is rarely seen in patients whose blood sugar is reasonably well controlled with insulin. Boils and carbuncles are believed to be more common in the untreated diabetic, but it is difficult to be certain on this point. Tuberculosis is a well-known complication of diabetes, and a careful watch for this must be kept on all patients whether the blood sugar is well or badly controlled, though the impression is gained that it is commoner in the latter.

(2) Does a high blood sugar tend to make the progress of another disease more rapid? The answer in this case can be more definite, for there is no doubt that a disease like tuberculosis of the lungs will progress more rapidly if the diabetes is uncontrolled. This is true of all skin conditions, and of all septic and gangrenous conditions, and every effort should be made to control the diabetes. It may not be possible to abolish the glycosuria entirely if the diabetes is difficult to control, and the fear of hypoglycaemic attacks is, I suspect, the reason for the question being asked. Hypoglycaemia may be due to two main causes. (*a*) The improvement in the lung disease may cause a diminished demand for insulin. This decrease is a good sign, since it shows that the lung disease is being better controlled. The care of a patient in a hypoglycaemic attack is simple, should be easily provided in a sanatorium, and should not, therefore, be feared in any way. It can cause difficulties only when patients do not recognize the early symptoms and have severe and unexpected attacks. These patients are fortunately few in number and in them glycosuria must be allowed, but it is a pity to allow glycosuria (even without ketosis) in all types of patients because of the fear of hypoglycaemia. (*b*) Attacks of hypoglycaemia may be due to errors in diet. It is most important that the diet should be supervised by a trained dietitian. This will ensure throughout the sanatorium a diet which is varied and well chosen. The diabetics will get a diet in which the carbohydrates are reasonably constant and well varied. The exact amount of carbohydrate which each patient needs must be discovered, whether it be 150 g. at a time when the appetite is poor, or 300 g. or more when the condition is improving. Sufficient insulin must be given to control the glycosuria so far as possible. If this can be achieved the patient will have the best chance of recovering from his lung disease, and surely the best is what he should be given, even at the expense of some extra trouble.

INCOME TAX

Amount of Refund Due

V. M. states that in the year to April 5, 1945, he earned £241 "pay" and had £39 tax deducted therefrom, and in the year to April 5, 1946, he will have earned £426 and have had £127 tax deducted. What refunds will he be entitled to claim?

⁂ On the facts stated—£14 for 1944–5, and £60 for 1945–6. These amounts will be increased if he has a claim to an allowance for the expense of a uniform.

Cost of Postgraduate Course

D. H. is in general practice and is taking a postgraduate course Can he deduct the expense in calculating his professional profits?

⁂ We are not aware of a specific judicial decision on this point and, as D. H. suggests, there may be some variation in practice as between one locality and another. Assuming that an expense of so personal a nature is not barred the principle involved seems to be that an expense incurred to *maintain* an existing standard of knowledge is a permissible deduction, but not an expense incurred to *improve* that standard. Obvious analogies are supplied by the application of the same fundamental distinction between "revenue" and "capital" expenditure to such expenses as the replacement of a car or the maintenance of the medical library. (If D. H. had been assessed under Schedule E the answer to his inquiry would almost certainly have been in the negative.)

Replacement of Car

W. K. finds it necessary to replace a ten-year-old car by a new one costing £400. What deduction can he claim?

⁂ (*a*) If he has not claimed and been allowed in the past a deduction for depreciation of the old car W. K. can claim to deduct as an expense the cost of replacement. That cost will be £400 less the amount (if any) received for the old car. (*b*) If he has been allowed depreciation, he cannot claim the cost of renewal, but can claim to deduct as an expense the excess of the cost of the old car over the total allowances for depreciation, and can also claim depreciation on the cost of the new car.

Sickness Insurance Benefit

"DELTA" inquires whether an annual amount payable under a sickness policy is liable to income tax.

⁂ We are not aware of any specific judicial decision on this point, but we understand that such sums are not liable to tax unless there are some special features bringing the payments into the scope of the tax.

Payment in Lieu of Board and Lodging

P. L. was engaged as an assistant at a salary of £425 per annum, it being understood that board and lodging would be provided. The employer was, however, unable to find accommodation in his own house and paid P. L. an additional £4 4s. a week in lieu thereof. Is this £4 4s. liable to tax?

⁂ Yes. The original agreement appears to have been replaced by the later one under which P. L. agreed to receive the £4 4s. weekly in cash, and that amount is "income" liable to tax.

LETTERS, NOTES, ETC.

Permanent Holiday Camps for Children?

Miss E. FRANCIS-MOSS (c/o 61, Oaklands Road, Cricklewood, N.W.2) writes: Evacuation of the city children to the country improved the health of the children immensely, and those who have returned to London since VE-Day were bonny, plump, well-developed children, who had learned to love the country, its open spaces and fresh air. Now they play in the streets and on bombed property, and fling bricks at each other for the sake of something to do. Is all the benefit that these children have gained through evacuation and country life to be thus lost, and are they to go back to the same low standards of health and development from which we took them? What use are all our educational plans and advantages if the individuals who should benefit cannot do so, owing to tiredness and listlessness due to a low standard of health? Cannot we arrange that the long summer vacation may be utilized with advantage, and that every city child has at least a month in the country? There are many Service camps and hostels all over the country at the present time which could be utilized for the scheme. Men and women of wide experience and ability would be needed to supervise the camps and to give helpful advice to the various personnel. Retired teachers would do this admirably. Students from our colleges and universities would probably volunteer to supervise the children and their activities, and students from the domestic science departments of our universities might manage the domestic part with the help of local employees, and would themselves gain much good experience. The W.V.S. would probably also help in the scheme. The scheme might mean a small increase in the rates, but surely it would be worth a little expense to see our children healthy and happy. In the long run it would be a gain, for the more spent in the prevention of sickness the less spent in the curing of it. I shall be pleased to receive any criticisms and remarks readers may wish to make.

Knyveton's "Diary of a Surgeon"

Major SAUL JARCHO, M.C., A.U.S., writes from the Office of the Surgeon General, Washington: The question of the authenticity of Knyveton's *Diary of a Surgeon in the Year 1751–2* was raised anew by one of your correspondents (April 21, 1945) and drew interesting replies from Prof. Miles Phillips and Dr. J. F. Blackett (May 19). May I take the liberty of calling attention to certain linguistic anachronisms which definitely establish the spuriousness of the *Diary*. These were noticed in the *New York Times Book Review*, Dec. 12, 1937: ". . . the author speaks of 'passers by,' whereas the eighteenth century would almost certainly have said 'passengers.' Other lapses are 'jungle,' which did not enter the language till 1776, 'pugilist' (1790), 'riddled' (1849), 'realistic' (1856), and 'intrigued,' which in the signification of 'interested' was first used in 1905."

Liver Extracts

Mr. W. B. EMERY writes from Glaxo Laboratories: I have only just seen in your issue of Oct. 6 a reply given under the heading of "Any Questions?" to a query about the use of liver extracts in aplastic anaemia or essential thrombocytopenia. First, you stated that refined extracts were more reliable than crude, due to greater care in clinical testing. We have already referred in some detail in a recent paper published in the *Journal* (Jan. 20, 1945, p. 75) to the differences between crude and refined extracts, and have indicated there that our crude extract is expected to pass the same rigid criteria of potency which are applied to our refined extract. In fact, every batch of both extracts is subjected to at least one and in many cases two or three separate clinical tests, albeit at different dose levels, consistent with the fact that refined liver extracts will produce satisfactory responses in much smaller dosage than crude liver extracts. Next, you stated that intensive liver treatment in a case of refractory pernicious anaemia would formerly have implied 4 c.cm. of refined liver extract every day. I think you would find on inquiry that the vast majority of doctors in this country would almost certainly not use a refined liver extract for *intensive* therapy, but that a crude extract would normally be used. This is probably chiefly a matter of prejudice, persisting from the time when refined extracts tended to be rather untrustworthy. In either case I would contend that a dose of 2 c.cm. of a *refined* liver extract every alternate day would be ample for any intensive course of treatment, and, with many extracts at present available, including our own, even this would be grossly excessive. The use of larger amounts would merely be a waste of liver. The statement that the injections would be supplemented to-day by oral proteolysed liver extract seems to be based only on the comparatively few cases recently reported by Davidson and his colleagues. So far as I am aware there is no evidence that oral therapy with dried stomach would not achieve the same results. I would also point out that oral therapy of any kind is very much more costly and wasteful of liver than parenteral therapy, which should certainly be tried in the first place.

Destruction of Adult Schistosomes in Man

Dr. F. GORDON CAWSTON writes from Durban: Evidence of the death of the male schistosomes through applying a course of antimony injections containing less than 0.75 g. of the metal, as first used by Dr. J. B. Christopherson in 1917, is far from conclusive. Without confirmatory signs the complement-fixation test is of no more value than a record of the eosinophils during and subsequent to treatment, and investigations are needed to show how far these apply to each sex. Before a line of treatment can rightly be enforced on native labourers such evidence of successful cure is desirable lest the dislodgment of the worms in the blood stream may result in obscure pathological conditions. A Transvaal district surgeon has raised the question how far it is best to leave patients untreated where a thorough course cannot be assured, and I have sometimes hesitated to do more than keep severe cystitis under control in little Indian girls of only a few months of age whose mothers relied on a badly infested pool for their water supply, thus hoping for the development of a natural immunity in due course. Microbic invasion spreading up from the bladder, especially following gonorrhoea and instrumental treatment before the parasites are dead, is the cause of most of the trouble in the ureter and kidneys, where, although ova are not uncommon as they are in the appendix, the adult worms seldom if ever occur.

Podophyllin for Warts

Capt. G. W. CSONKA, R.A.M.C., writes: In your "Any Questions?" column (Oct. 27, p. 592) a 25% suspension of podophyllin in mineral oil is recommended for the treatment of soft warts. I have had some experience with this method when treating condylomata acuminata, and was soon forced to modify it due to the frequency and sometimes severity of the chemical balanitis which followed. First I used 5% podophyllin powder in tannic acid, as advised by Major H. Haber, R.A.M.C., and had no reactions; the effect on the warts was definitely less strong. I now use 10% podophyllin in liquid paraffin, and tell the patient to wash the area in four hours. All but two cases responded gratifyingly to the first application, and the failures lost their warts after a second application. It is essential, however, even with this modified treatment, to clear any coexisting balanitis prior to the attack on the warts.

Correction

Dr. J. E. BANNEN writes: In my letter (Nov. 10, p. 665) on "Sequelae of Emphysematous Lung" I did not make myself clear on the differential diagnostic test between pneumoperitoneum and retroperitoneal gas. This should read: In pneumoperitoneum the gaseous sites move to the uppermost limiting parts when the patient is changed from the vertical to the lateral decubitus, but retroperitoneal gas remains fixed in its loose areolar space.

MEDICINE AND THE STATE

WITH SPECIAL REFERENCE TO THE EMERGENCY MEDICAL SERVICE*

BY

The Right Hon. **WALTER ELLIOT**, *M.C.*, D.Sc., F.R.C.P., F.R.S.

The State—the organized community—finds itself always interfering more and more with the individual in two things, education and medicine—the development of the mind and the care of the body. The doctor and the teacher are two figures over whose appointment, qualifications, and conduct the community continually demands a certain control. As the community increases in power the balance of this control requires the most careful scrutiny. In its control over the teacher the community—which is to say the official—has now gone to very great lengths. Its control is not yet complete. It is not yet, for instance, a punishable offence to send a child to any place of instruction distant more than a certain number of yards from its doors, or to give it a course of instruction other than that prescribed by the State. But the trend of administration is certainly in that direction. We have seen Glasgow Town Council attempt to prohibit any children being sent to Glasgow High School except those who happen to live around its doors, even though the parents might be willing to compensate authority for this slight disturbance of routine. That is, of course, the direct contrary of the principle of individual choice which has so far had at least lip-service paid to it in the case of medicine. It seems unlikely that this principle will be allowed to survive in one sphere if it is destroyed in another, and it is well worth the while of the profession of medicine to look from time to time over the wall to see what is being done to its sister art, the profession of teaching.

I think most of us here believe that the all-powerful authority of the State, convenient though it might be to wield for us as individuals, is too crushing and deforming a power to be used to govern those delicate reactions of mind and body on which the practice and the progress of the medical art depend. Medicine is, and must always remain, a more experimental, a more dubious art than that of teaching. The status of the pupil (an ancient, an honourable, and a well-understood status) is almost literally child's play compared with the status of the patient. The status of the pupil derives generally from the relations of adults with the immature. The status of the patient must regulate the relations of an adult with an adult. To entrust an adult with authority over another adult, authority of such a sweeping nature as that of a doctor, is always a very risky thing to do. That authority may, for instance, at quite an early stage (say in delirium), involve actual physical restraint. In the case of lunacy—and that is, after all, only a matter of the signature of two men or even of one man—it may turn into imprisonment for life. For the community to organize and systematize this power into a single solid, compulsorily united front would seem a great peril to the individual. Doctors do not desire this power. It is proffered to them and at times stridently thrust before them by the State. From time to time, however, such organization and such combination are inevitable, as in time of war. The motto of those working in such an emergency, considering the consolidation of such power, should always be less rather than more, and temporary rather than permanent.

Formation of the E.M.S.

It is interesting to look at one recent experience and see how the State, required by force of circumstances to carry out a great unification of the medical services of this country, proceeded. I refer to the Emergency Medical Service, particularly in its hospital aspects, during the war.

I should like first of all to direct your attention to its title. The title focused and riveted attention, and was intended to do so, upon the very fact that these measures were emergency measures to deal with an emergency situation. The next thing to note is that the scheme was brought into being along empirical lines, not proceeding on any preconceived abstract theory, but dealing with the situations as they occurred. So far as I know, each of us responsible for its inception tried first in our approach to envisage the problem and then to find an appropriate solution. This differed from what seems to be the motto at present—namely, to produce a solution and then to go about to find a problem which it will fit.

The Emergency Medical Service arose out of the approaching danger of war, and more particularly out of the danger of war in the air with its necessary consequence of large numbers of casualties within our own shores. It was considered likely by the Service authorities that very large numbers of casualties might arise, and would certainly have to be prepared for, in the earliest days, or even hours, of such a war.

The first solution tried was through the local authorities. The first Government Act was the Air Raid Precautions Act of 1937. This placed upon the local authorities the responsibility for framing air-raid precautions schemes, including casualty services. In 1938 it became clear that adequate hospital provision simply could not be made on such a basis. For one thing, local government boundaries were often completely inappropriate. It was therefore laid down by the Government that the Minister of Health in England, and the Secretary of State for Scotland, should be responsible for providing an Emergency Hospital Service. Early in 1939 the administration of the related first-aid, and ambulance, services was transferred from the Home Office to the Ministry of Health. I was at the time Minister of Health and therefore saw more of the English end; and as the weight of attack fell chiefly on the southern half of our island, and more particularly upon the Home Counties and the London area, I shall use several illustrations drawn from the South.

Our scheme was, fundamentally, to expand the existing hospital system to the utmost, and in particular to secure the co-operation of local authorities and voluntary organizations to the greatest possible extent, looking only to the most efficient solution of the problem, and not to preconceived ideas as to how this should be brought about.

The first step obviously was a survey of the existing accommodation, with careful attention to possibilities of expansion. (I say " obviously "; but it had not in fact previously been done.) All the ordinary hospitals, and in addition mental hospitals, public assistance institutions, sanatoria, etc., were surveyed. In all about half a million " hospital " beds were brought under review.

The next step was to obtain the co-operation—and I stress the word *co-operation*—of local authorities and voluntary organizations, both in placing accommodation at the disposal of the Government and in expanding accommodation where it was desired. The supply of medical personnel was tackled with the co-operation of the British Medical Association, and steps were taken to establish an auxiliary nursing service. Emergency pathological and blood transfusion services were also arranged for with the assistance of the Medical Research Council. All this was done in advance of statutory authority, and it was fortunate that this was so. The position was later regularized by the Civil Defence Act; but this was not passed till July, 1939, while the war, as you will remember, came in September. Lacking the steam-roller of the statute, we really did have to proceed by agreement. This meant good will. The Emergency Hospital Service was provided for by Part VII of the Civil Defence Act. The transfer of first-aid posts and similar services was left to arrangement between Ministers under Section 1 (3). In view of the shortness of time available it will be seen that it was wise not to embark upon previous discussions as to abstract principles. Up till that time—till the passing of Section 50, to be exact—the Minister had no power in actual fact to do all the things he was doing—to acquire land, buildings, and equipment, and, a more ticklish business, to enter into agreements with local authorities and voluntary hospitals. But about 70 to 80% of the hospitals, municipal and voluntary, came within the scheme.

---

* Address to the Edinburgh Royal Medical Society, Nov. 23, 1945.

A Difficult Problem

What was the actual problem? It was very briefly this: that the Air Ministry informed us that the liability was an air assault on a scale of 25,000 casualties per 24 hours—going on, night after night, for ten days and nights on end, or possibly more. They considered that provision would have to be made for some 300,000 bed cases in Great Britain—apart from the killed and hopelessly injured. This enormous casualty list had to be regarded as an immediate liability from the very earliest hours of the war. It was clear that this altogether transcended any ordinary scale of battle casualties which we had ever known or prepared for; it was, for instance, two or three times as great as the whole fighting strength of the British Expeditionary Force.

The first decision taken, therefore, was to mobilize on the civil side and not on the military; and this, as will appear, involved mobilizing on the voluntary organizations rather than on the State. We had to postpone, for instance, the call-up of medical and nursing personnel from civil to military hospitals, which had been till then a cardinal feature of war mobilization. To meet this liability the achievement was considerable. In the first week of Sept., 1939, 190,000 beds were available to receive casualties. This was found a useful working figure, though rather excessive. At March 31, 1944, there were in E.M.S. hospitals in England and Wales about 40,000 beds vacant, ready to receive; 51,000 beds could have been cleared and 24,000 more staffed quickly if necessary. This gives a total of 115,000 beds to which longer-term reserves could have been added.

The scheme provided for 100,000 beds to be obtained from the 500,000 previously reviewed, for 100,000 to be obtained by setting up additional beds in existing institutions, and for 40,000 beds to be provided in new hutted hospitals, mostly as annexes of existing institutions. To make these beds usable for classes of cases not previously treated—e.g., surgical cases—a process of up-grading was set on foot: provision of operating theatres, *x*-ray rooms, improved sanitation, and so on. This up-grading was paid for in the case of the local authorities largely by the Exchequer, and in the case of the voluntary hospitals wholly by the Exchequer. Such expenditure had of course to be approved by the Department. Protection against bombs was also carried out. All this involved Exchequer payments of something between two and three million pounds—I think you will agree, a very moderate sum.

The hutted hospitals, although mainly in the grounds of existing institutions, cost some four million pounds for the first 37,000 beds. About another 20,000 were later provided —10,000 civil and 10,000 military. All this was considered by the Select Committee on National Expenditure reporting in 1941. They said that after visiting a number of these hutted hospitals they were impressed by the standards of construction and equipment which have been secured at so low a cost, and that "the Ministry and the Department of Health for Scotland are to be congratulated on an achievement which might well be studied by local authorities." They found that the average cost per bed of hutted hospitals built as independent units was £250, of those built as annexes £100. The cost per bed of a hospital built on peacetime standards was of the order of £1,000.

The Emergency Medical Service was staffed in the year ending March 31, 1941, by 1,737 doctors employed whole-time and 564 paid on a part-time basis. In addition 4,584 doctors were enrolled on a sessional basis. In that year—March, 1940, to March, 1941—the total expenditure of the Ministry of Health on the Emergency Medical Service, the Emergency Hospital Scheme, and allied measures to deal with casualties and disease was estimated at £15,703,000. This excludes first-aid posts and A.R.P. street ambulances. Again I think it may be said that this extensive organization was not only on the whole smoothly put through but was remarkably inexpensive. How, then, was its administration carried on?

Administration of the E.M.S.

Certain points are worth noting. I have mentioned the staffing of the scheme. The proposals for an Emergency Medical Service were worked out in the spring and summer of 1939, after long discussions with the Central Emergency Committee of the British Medical Association (which became during the war the Central Medical War Committee). The salaries of whole-time officers corresponded roughly to the rates for officers in the R.A.M.C. The basic grade of a "Medical Officer" corresponded to that of "Captain"; the grade of a Specialist to that of "Major," with corresponding rates on higher levels. The junior grade of "House Officer" carried a salary below that of a Lieutenant, R.A.M.C. It was not considered justifiable to pay at so high a rate for junior officers of this class.

The Group Officers (the Deans or members of the consulting staffs of the teaching hospitals) were organizing lists of practitioners when war broke out. Practically all the practitioners on the Group Officers' lists reported for duty whether they had received a formal letter or not. In the circumstances of the possible 300,000 casualties previously mentioned their services were all accepted. But this led to the enrolment of 2,156 practitioners. All these were subject to the rules attaching to temporary officers of a Government Department. It will be recalled what trouble had then to be taken almost immediately to get out of this whole-time State Medical Service when the emergency did not materialize, and to transform it into something permitting of private practice.

The nursing personnel was also expanded under a Central Emergency Committee for the Nursing Profession. A register was compiled of those who would be willing to serve in an emergency. In August, before the war, the register covered 10,000 trained nurses, 4,000 assistant nurses, and 55,000 auxiliaries (14,000 trained). By 1940 the numbers were 15,000 trained nurses, 6,500 assistant nurses, and 100,000 auxiliaries (26,000 trained). This figure includes 12,000 members of the St. John Ambulance Brigade and the British Red Cross Society who had already received training from those bodies. The cost of enrolling, registering, training, and equipping 100,000 members of the Civil Nursing Reserve was reckoned at £250,000 over 2½ years. This, of course, does not include the wages paid to members once they were called up.

The organization of this extensive scheme turned very largely on voluntary bodies. It was a regional organization, and the two official figures in each region were the Medical Officer of Health and the Group Officer. These worked under a Hospital Officer, who was a medical officer of the Ministry and whose task was to supervise the expansion of the hospital system and to control the movements of casualties and the operation of the scheme under war conditions. The Group Officer—the key of the whole structure—was the Dean or other member of the consulting staffs of the teaching hospitals in the region.

Organization on the voluntary institutions reached its peak point in the most threatened area—namely, that of London. For the purpose of the Emergency Hospital Scheme a special hospital administration was necessary, for which neither the London County Council organization nor the London Borough organizations were found appropriate. The object was to bring into a single working scheme a large number of hospitals of very diverse character and to secure a degree of co-operation between them which had never existed in peacetime. All this was to be operated under battle conditions—conditions of which no one had had the least experience and which it was impossible even approximately to predict. No one, for instance, could forecast the reactions of the civil population under such conditions.

In these circumstances we built a great part of the whole scheme upon the professional authority, the prestige, and the administrative competence of the heads, nursing and medical, of the great voluntary teaching hospitals; and we were not disappointed.

The actual physical area of the London Region comprised about a quarter of the population, and was, of course, in much the most heavily threatened position. The London Region, a great circular area, was divided into ten triangular slices or sectors, as it might be slices of cake. Each slice or sector except one had at its tip one of the voluntary teaching hospitals. Each Sector was in charge of a Group Officer, who was a distinguished physician or surgeon on the staff of that hospital. He was responsible, under the Director of Emergency Medical Services, London and Home Counties, for the treatment and movement of all cases coming within the Emergency Hospital Scheme. He administered the staff, the doctors, and the nurses of all hospitals within the scheme. He advised on questions of up-grading, and of approving annexes to the sector hospitals. On him lay the duty of co-operating with the adjoining Sectors and with the adjoining Region or Regions.

He was assisted in the discharge of these duties by two medical officers who might act as his deputy. He had also two matrons and two lay officers. One in each pair represented the voluntary hospitals; one in each pair represented the municipal hospitals. In the smallest of the Sectors there was only one representative in each of the three grades just mentioned. This economy was secured by dispensing with the municipal representatives. Each Sector had in addition a "bureau officer" and a subordinate staff varying from 15 to 21.

It is fair to say that in 1941 the Select Committee on National Expenditure, some of whose comments have already been referred to, considered that in view, among other things, of the difference in size of the Sectors—the smallest containing 3,000 emergency beds and the largest some 11,500—some reorganization should be undertaken. They also felt that the Sectors had worked too much as independent units, although they recognized the object of the appointment of the Director and his two assistants to co-ordinate the work of the Group Officers. They considered, however, that the organization should be still further co-ordinated and centralized. But it is worth while to put on record their opinion of the Civil Defence Services which they were reviewing, and in which the Emergency Hospital Services were included. They said: "They have been put to the test of experience. Their need has been proved, their efficiency has been demonstrated; their courage has won the admiration of the world. Such criticisms as we [the subcommittee] offer are solely directed to obtaining the greatest economy compatible with efficiency." It is significant, and it has perhaps scarcely received sufficient attention, that these tributes are paid to an organization, in the case of the hospitals, in which the teaching chiefs and the voluntary hospital matrons, previously untried in these great administrative tasks, were asked to play, and did play, so large a part. The latest tribute was paid no longer ago than Sept. 7 of this year by the *Times*, which said: "With all its faults the emergency hospital scheme was an outstanding success; it came through the severest tests with fine efficiency."

In so vast a preparation many mistakes were inevitably made, and from these, also, useful lessons may be learnt. One which impressed itself most strongly upon me was the danger of over-attention to, or misinterpretation of, central direction. The case of the tuberculosis hospitals was one of these. The direction was given to clear beds at the onset of the emergency—a direction familiar to those of us who have ever, in forward areas, awaited with apprehension the opening of a battle. The directive words were: "To send home all patients no longer urgently in need of hospital treatment." It was intended that these words should apply only to those whose health would not be prejudiced by relinquishing hospital treatment, and also who had accommodation to go to at home. In the event, many cases were cleared whose health was, in fact, not able to stand discharge from hospital and whose accommodation at home was quite insufficient. Similar cases will be in the recollection of many. Much effort was needed to restore the position.

In practice it may be said that the scheme worked flexibly. When the anticipated air raids did not occur the hospitals were again receiving the ordinary sick in the winter of 1939–40. After Dunkirk large numbers of casualties were received on the south-east coast, and the London scheme was tested in reverse, since the movement of cases was towards London and not away from it. Later on in that year the full weight of air attack fell upon London and the southern areas. It was dealt with. Later, a wide extension of the classes of cases admitted took place, and these included civil defence workers, transferred war-workers, transferred sick, and evacuees.

In 1940–1 some £3,000,000 (£2,913,900) was spent on provision and maintenance of additional hospital accommodation, and some 7½ million pounds (£7,671,500) on payments in respect of reserved hospital beds. From Sept. 22 to Dec. 29 (one quarter) £1,200,311 was paid on account for "reserved" beds empty (53,000, declining to 24,000) and £87,268 for occupied beds (3,000, declining to 2,500).

Post-war Hospital Policy

On Oct. 9, 1941, the Minister of Health indicated in the House of Commons the general principles on which the Government proposed to base post-war hospital policy. These were *(a)* that there should be a comprehensive hospital service providing for each treatment appropriate to his need; *(b)* that the duty of providing such a service should be laid on the major local authorities in close co-operation with the voluntary bodies; and *(c)* that the service should be designed by reference to areas substantially larger than those of individual local authorities. These were the main conclusions, though there was an important proviso that special State aid for teaching hospitals, probably in the shape of increased educational grants, must be contemplated.

The whole hospital question, so far as Scotland was concerned, was reviewed in 1942 and 1943 by the Hetherington Committee (Jan., 1942, to Aug., 1943). The position in Scotland differed somewhat from that in England because our native caution had produced a hospital situation pre-war in which our hospitals were better endowed but fewer proportionately than those in England, so that as part of the preparations for war seven new hospitals providing some 7,000 beds had to be built. This figure for peacetime standards, said the committee, would be scaled down to about 5,000.

The Hetherington Committee came to the conclusion that these hospitals presently administered directly by the Department of Health should be transferred to local health authorities, though not necessarily to the authority in whose area any particular hospital was situated. They did not wish to exclude the transfer of a hospital to a voluntary body or to a combination of a voluntary body with a local authority. The committee's views on administration—in particular on finance, which is the keystone of administration—were of much interest. The main body of the committee suggested either a subvention from the local authorities or a direct Exchequer grant. In either case the distribution of the grant should be under committees appointed not by the local authorities but by the Secretary of State. The chairman, Sir Hector Hetherington, suggested a straight grant of State assistance, payable on a formula to every voluntary hospital which would accept the responsibility of providing an efficient and economically administered service as part of a general scheme. The general view of the whole committee was that there should be as little interference with the voluntary hospitals, either in their administration or in their finance, as was possible, particularly by local authorities.

The story may be brought up to date by the decision of the Government, announced in September of this year, to seek power to carry on interim arrangements while the "run-off" of the special war responsibilities continues.

The number of beds reserved for E.M.S. cases in England and Wales has fallen from 187,000 in Jan., 1941, to 63,000 to-day. This has meant a corresponding limitation in the income of the voluntary hospitals. The present decision is to make Exchequer grants from next April "to such voluntary hospitals as establish their need for such assistance in order to maintain proper services."

It is remarkable that those two lines of investigation—one purely practical and empirical carried out over years on a vast scale, and the other a theoretical review carried out by a distinguished committee—should converge on this point of the excellence of the work of the voluntary organizations and the desirability of leaving it alone as much as possible. Their work is excellent, not merely in the quality of the medical service given, but in the quality of the administrative talent available. I have already pointed out that in the most critical region of all, that of London, the solution which worked over a great part of the field was not to put the voluntary hospitals under the local authorities, but to put the local authorities under the hospitals. The fact is, that administrative talent of a high quality is developed under the very decentralized conditions of the voluntary hospitals to an extent inevitably greater than that reached in the highly centralized large municipal administrations. This seems particularly true in the case of the matrons.

The conclusion from all this seems to be that if the State leaves the self-governing institutions of medicine to do the actual work so far as is possible, making that work financially possible so far as the State deems it necessary, the State will secure the best efficiency of service and the best economy in finance. In addition it will develop opportunities for training talents which are useful in time of peace and invaluable in time of war.

Some Further Considerations

The omens, however, are not entirely favourable. An arrangement in the field of education, similar to one of those which have been suggested in the field of health, has existed in England for many years. I refer to the direct-grant schools. A direct-grant school is one which gets a grant direct from the Board of Education and is not under the local education authority. But the Minister for Education in England last month showed a very north-windy attitude towards this solution. The tolerance for which this country has been distinguished in the past, its power of putting up with apparent incompatibilities, seems to be weakening. It is obviously a disadvantage to us all that this should be so. It is especially a danger in the case of the highly organized communities of which we form part. Unless communities can tolerate in their bosom—tolerate and indeed welcome—the same sort of differences that exist inevitably between individuals, the community is in for a very poor time.

This is above all things true in the relation between Medicine and the State. Personally, I read all the antivivisection and antivaccinationist literature I can get hold of. I do my utmost to practise a robust disbelief in remedies and theories, new and old. I still remember with reverence the teaching of that excellent professor Ralph Stockman, whose first query in observing any case was: "What will happen if we do nothing?" and who once electrified his class by the query: "How does a tiger treat a case of blood-poisoning?" "Do not laugh, gentlemen," he said: "it is a very serious business for the tiger. He lies perfectly still and drinks cold water." I even read the medical opinions of Mr. Bernard Shaw, deeply as I disagree with most of them. But to-day we find Mr. Bernard Shaw and the other iconoclasts supporting a line of thought which certainly will pay little enough respect to his highly individualistic ideas on the subject of medicine, any more than it will to his ideas on a proper system of education.

Well, there is nothing for it but to maintain the position that exceptions, contradictions, and anomalies are part of the make-up of man's mind, as of man's body. A system of medicine which does not recognize and admit these facts is a system of medicine which does not correspond to the facts. But it is paradoxical that the position of the layman in medicine—for, after all, the position of the voluntary hospital, with its lay Board of Governors, is the position of the layman—will have to be contended for, against so much opposition, by medical men themselves.

THE RELATION BETWEEN CONGENITAL OBLITERATION OF THE BILE DUCTS AND ICTERUS GRAVIS NEONATORUM

BY

M. O. SKELTON, M.B., Ch.B.

AND

GEOFFREY H. TOVEY, M.D.
Major, R.A.M.C.

(From the Department of Pathology, University of Bristol, and the Army Blood Transfusion Service)

Icterus gravis neonatorum and congenital obliteration of the bile ducts are two conditions which cause jaundice in the new-born. Most textbooks of diseases of children imply that the differential diagnosis between these two diseases is comparatively straightforward and that they bear no relationship to one another. In 1943, however, Lightwood described three cases of icterus gravis in which the onset of the jaundice was delayed and which, when it once appeared, lasted an inordinate time—for 3½ weeks, 11 weeks, and 3 months respectively. The child in whom the jaundice lasted 3 months ultimately died, and at necropsy the liver showed plugging of the canaliculi with masses of bile and an accompanying hepatic fibrosis which amounted to biliary cirrhosis. Clinically these children had shown persistent acholia and the picture of an obstructive type of jaundice simulating congenital obliteration of the bile ducts. Lightwood questioned whether the plugging of the canaliculi and ducts with bile thrombi in icterus gravis might not be followed in some cases by organization of the thrombi. This would presumably lead to fibrosis of intra- and extra-hepatic ducts so as to produce finally a type of lesion which, seen at necropsy, might well be diagnosed as congenital obliteration of the bile ducts. During the past three years we have encountered several cases of haemolytic disease of the newborn in which there have been either clinical signs simulating congenital obliteration of the bile ducts or a history of this condition in other members of the family (see Table), and which illustrate the association that obtains between these two conditions.

Types of Biliary Obstruction associated with Icterus Gravis

It would seem that the biliary obstruction in children with icterus gravis may take one of two forms: (A) blockage of one of the larger bile ducts with inspissated bile, or (B) conversion of the bile ducts into a fibrous cord.

Examples of Type A.—The child of family Hi (see Table) was at first diagnosed as a case of congenital obliteration of the bile ducts, but because of the deaths of the previous siblings and the presence of some degree of anaemia (R.B.C. 4,180,000 per c.mm. 15 days after birth) Rh investigations were made. Rh incompatibility was found to be present, but despite a blood transfusion the jaundice persisted. A laparotomy was performed for biliary obstruction at the age of 7 weeks, and an obstructing mass of inspissated bile was dislodged from the lower end of the common bile duct by gentle manipulation. Gentle pressure upon the gall-bladder showed the biliary tree now to be patent, and the abdomen was closed. After this operation the jaundice disappeared, bile appeared in the stools, and the child made a complete recovery. The child of family Ha. was admitted to hospital at the age of 6 weeks with severe anaemia, jaundice, and clay-coloured stools. A blood transfusion to correct the anaemia was succeeded by the disappearance of jaundice and the presence of bile in the stools. It is probable that a similar obstructing mass had become dislodged spontaneously after the blood transfusion.

Two almost exactly similar cases have been described by Davidsohn (1945), and Ladd (1935) cites that in 5 of 15 babies upon whom he operated for congenital obliteration of the bile ducts a similar inspissated mass was the causative factor. Rh investigations were in keeping with the diagnosis of haemolytic disease in Davidsohn's cases, and it seems likely that those described by Ladd originated as cases of icterus gravis but that the clinical features of haemolytic disease passed later into those of congenital obliteration.

Examples of Type B.—The other type of biliary obstruction associated with icterus gravis—namely, replacement of all or part of the extrahepatic duct system by a fibrous cord—is illustrated by the child of family G. E. in our series and by the second child of family M. Pasachoff (1935) also has described a negro child with icterus gravis who died at 7 days with erythroblastosis foetalis and congenital fibrous obliteration of the common duct.

Mechanism

It has been suggested by Hawksley and Lightwood (1934) that the probable mechanism of obstruction of the bile ducts by plugs of bile in cases of haemolytic disease is that the bile produced by the liver is very viscid and tends to stick in the intra- and extra-hepatic ducts. We have noticed, however, in 11 cases of icterus gravis studied histologically that the plugging of canaliculi by bile thrombi is commonly associated with evidence of hepatic cell damage—a severe and significant degree of cloudy swelling, or fatty infiltration, or actual cell necrosis. In the damaged liver of infective hepatitis there is marked stagnation of bile in the fine intralobular canaliculi just outside the areas of maximal necrosis, which would suggest that a similar obstruction by necrotic and damaged cells is largely responsible for the production of the biliary thrombi in icterus gravis. Once these thrombi have formed they may aggregate to produce an obstructing mass in the extrahepatic bile ducts, the final effect being to add an obstructive element to the jaundice caused by the haemolysis.

Details of the Cases

Family	Pregnancy	Date	Clinical Features	Necropsy Findings	Rh Investigations		
					Father	Child	Mother
G. E.	1	1941	Normal; alive and well		Positive	Positive	Negative
	2	1942	Jaundice 1st day; bile in urine. Died aged 2 days	Erythroblastosis. Marked erythropoiesis liver and spleen. Fibrous obliteration of common bile duct. Kernicterus		Not examined	No Rh antibodies demonstrable 3 years after birth of affected child
M.	1	1939	Normal; alive and well		Positive	Positive	Negative. Rh antibodies in mother's blood 3rd and 4th pregnancies
	2	1940	Jaundice 1st day; bile in urine; clay-coloured stools. Cholecystogastrostomy performed for fibrous occlusion of common duct. Recovery			,,	
	3	1943	Jaundice 2nd day. Died 4th day	Erythropoiesis. Bile plugs in small ducts and canaliculi. Kernicterus		,,	
	4	1944	Jaundice 2nd day. Died 3rd day	Slight erythropoiesis. Cloudy swelling of liver cells. Kernicterus		,,	
L.	1	1933	Full-term. Died neonatal asphyxia		Positive	Not examined	Negative. Rh antibodies in mother's blood at 6th pregnancy
	2	1935	Neonatal jaundice, but recovered without treatment; alive and well			Positive	
	3	1936	Miscarriage at 3 months			Not examined	
	4	1938	Jaundice. Died 10th day	Congenital obliteration of common bile duct		,,	
	5	1943	Miscarriage at 3 months			,,	
	6	1945	Jaundice 1st day. Hb 89% at 48 hours. Biphasic van den Bergh. Bile in urine. Recovery after transfusions			Positive	
Ha.	1–5		First 2 children normal; next 3 jaundiced but recovered without transfusion		Positive	Not examined	Negative. Rh antibodies present in mother's blood at 6th pregnancy
	6	1945	Increasing jaundice from shortly after birth. Admitted to hospital at 6th week. Anaemic; clay-coloured stools; bile appeared in stools after blood transfusion. Recovery			Positive	
Hi.	1–3	1941 1942	Three premature children Died shortly after birth		Positive	Not examined	Negative. Rh antibodies present at 4th pregnancy
	4	1944	Jaundice 2nd day. Bile in urine; no bile in stools. Van den Bergh—direct positive. Operation at 7 weeks for biliary obstruction. Inspissated mass dislodged from common duct. Recovery			Positive	

Occasionally an additional factor is present in significant damage to the bile-duct epithelium, as described by Wanstrom (1933). The biliary epithelial cells become swollen, thus tending to aggravate the condition, and desquamated epithelial debris lying free in the lumen of the bile ducts may further add to the obstruction. We have seen a similar biliary damage in one instance.

In some cases of icterus gravis of long standing biliary stasis may occur, producing a picture of hepatic cirrhosis very similar to that of congenital obliteration. This is the type of case described by Lightwood in 1943.

It is open to speculation whether the complete fibrosis of the common duct found in case G. E. of our series can be attributed to organization of a plug of inspissated bile similar to that found in other cases. The child died when only 2 days old, and it is our belief that although the hepatic cell damage occurs *in utero* in cases of icterus gravis and is probably due to an Rh antigen–antibody reaction occurring on the cells themselves, yet the biliary thrombi do not appear until extra-uterine life. It is rare for cases of icterus gravis to be jaundiced at the moment of birth; usually clinical icterus does not become apparent for some hours after. This absence of jaundice at the time of delivery is probably accounted for by the fact that while the child is in the uterus it is not called upon to excrete its own bilirubin but this is excreted by its mother, as postulated by Hampson in 1929. Once the child has to lead a separate existence, however, its liver damage becomes manifest and the events previously described take place.

If this be so, then there would be no time for biliary thrombi to have caused the fibrosis found in a 2-day-old child, and this particular instance cannot be satisfactorily explained on that hypothesis. There seems to be some other factor that requires explanation. Buchan and Comrie (1909), in one of the earliest anatomical studies in icterus gravis, described obstruction of the lower end of the common duct and of the ampulla of Vater in two of their five cases. This obstruction was due to swollen biliary epithelium beneath which was an infiltration by inflammatory cells. McGibbon (1912) has described a similar case, and these may represent a connecting stage between the two forms of bile-duct obstruction in icterus gravis.

The question may be raised as to the frequency with which other congenital abnormalities may be associated with haemolytic disease of the newborn, thus suggesting that this latter type of congenital obliteration may be caused by some general genetic incompatibility rather than be the result of an Rh antigen–antibody reaction occurring *in utero*. In a series of 44 cases studied clinically or at necropsy we have seen no associated congenital abnormalities other than those of the bile ducts, and Harrison and Meacock (1945) found no evidence of Rh-incompatibility in a group of 25 infants with such major congenital abnormalities as anencephaly, hare-lip, etc.

We do not suggest, of course, that all cases of congenital obliteration of the bile duct are associated with erythroblastosis foetalis; those cases of congenital obstruction with anomalous development of the biliary tract or with other malformation such as transposition of the viscera are almost surely developmental. However, the fact that some of them appear to be associated with icterus gravis is of practical importance. It cannot be too strongly stressed that any family showing a history of congenital obliteration should be examined for evidence of rhesus-incompatibility. Only in this way can preparations be made to anticipate haemolytic disease occurring in any subsequent child.

Since obstructive jaundice from plugging of the bile ducts with inspissated bile does occur in some instances, we have recently started the practice of massage over the gall-bladder region, twice daily, in cases of icterus gravis as a prophylactic measure in the hope of avoiding impaction. This we accomplish by inserting the tips of the fingers gently but firmly under the right costal margin, with the child in a sitting position, and allowing it to cry or breathe out forcibly against them. It is hoped that by this method either an actual or a reflex contraction of the gall-bladder will help to maintain a flow of bile through the common bile duct and hence withdraw bile from the intrahepatic canaliculi.

Summary

Evidence is adduced which suggests that certain cases of so-called "congenital" obliteration of the bile ducts occur as sequelae of icterus gravis neonatorum. Various mechanisms are suggested to account for the obstructive element in this disease, and the importance of recognizing this feature of haemolytic disease is stressed.

We wish to express our thanks to Prof. T. F. Hewer for his advice and help in this work and for providing material from one of his cases, which appears in this series. We also wish to acknowledge our gratitude to Dr. Beryl Corner and Dr. F. W. Lewis for material from two cases, and to Mr. S. A. Edwards and Mr. R. Polding for technical assistance.

THE Rh FACTOR AND BLOOD TRANSFUSION

OBSERVATIONS ON A GROUP OF Rh-NEGATIVE INDIVIDUALS TRANSFUSED WITH Rh-POSITIVE BLOOD

BY

WILLIAM CURRY MOLONEY, M.D.
Major, M.C., A.U.S.

This paper is concerned with Rh studies on 138 wounded American soldiers transfused with whole blood at the 163rd (U.S.) General Hospital. Of this group 18 were found to be Rh-negative; these cases were investigated for the presence of Rh antibodies and also in regard to the survival of Rh-positive cells in the circulation of Rh-negative individuals.

Methods and Materials

The techniques for Rh testing and for the detection of Rh antibodies were carried out according to the methods described by Taylor, Race, Prior, and Ikin (1942). The test for blocking antibody was that of Wiener (1944). Some of the Rh-testing serum was obtained from the Army Medical School, Washington, D.C., but the greater part of this work was carried out with potent human anti-Rh sera made available through the kindness of Dr. R. R. Race and the late Dr. G. L. Taylor, of the Galton Laboratory Serum Unit, Department of Pathology, Cambridge.

The great majority of the patients had severe wounds of the limbs which necessitated relatively long periods of hospital treatment, and all but a few cases were available for repeated Rh tests. All except one patient (Case 5) had received Group O blood in advanced medical units before admission. Records of these transfusions were meagre, and consisted usually of a note on the amount of blood and the date administered. Nearly all the blood used for transfusions at this hospital was obtained from the Blood Bank of the Department of Pathology, University of Cambridge, and the Regional Transfusion Service (British) in Cambridge. In this blood, glucose–disodium citrate mixture was used as the preservative, and the blood was not stored longer than two weeks before administration.

In the forward medical units of the U.S. Army the blood used was supplied through the European Theatre of Operations Blood Bank. Some of this blood came from the U.S., preserved in Alsever's solution; the blood drawn in the European theatre from U.S. Army personnel was preserved in a citric acid–sodium citrate–glucose mixture.

Results of Studies

Of the 138 patients studied, 18 (13%) were Rh-negative. These Rh-negative cases may be considered in three groups.

Group I

The patients in this group were given known Rh-positive blood at this hospital. The observations on these 6 cases (Nos. 1 to 6) furnish the most important data in this investigation.

Case 1.—Owing to retained Rh-positive cells from a transfusion 30 days previously, the patient was considered to be Rh-positive. He was given 1,700 c.cm. of Group A Rh-positive blood, but two weeks after the last transfusions the Rh test was only moderately positive and there were many unagglutinated cells. On the 23rd day following the last transfusion very few Rh-positive cells were found, and a test on the 29th day showed a complete absence of Rh-positive cells. A febrile reaction occurred during the second transfusion at this hospital, but no evidence of haemolysis was observed in the urine or plasma. Since subsequent transfusions with the same type of blood gave no difficulty, it was assumed that this reaction was pyrogenic in nature. Tests for blocking and agglutinating antibodies were negative.

Case 2.—This patient showed no retained Rh-positive cells 41 days after a transfusion of known Group A Rh-positive blood. Since no tests were carried out at an earlier date it is not possible to say how much more rapidly the Rh-positive cells were eliminated from his circulation.

Case 3.—In this case the Rh test was weakly positive one month after 1,500 c.cm. of blood had been given in France. Transfused with 500 c.cm. of a known Group A Rh-positive blood, 8 days later there were but a few Rh-positive cells left, and 16 days after the transfusion no Rh-positive cells were detectable.

Case 4.—Owing to a transfusion 12 days before admission this patient was thought to be Rh-positive. He was transfused with 500 c.cm. of Group A Rh-positive blood; the Rh test 34 days later revealed no Rh-positive red cells. As in Case 2, earlier testing might have demonstrated more rapid elimination of Rh-positive red cells.

Case 5.—No transfusions were given previous to admission. He was found to be Rh-negative, but nevertheless was given 500 c.cm. of Group O Rh-positive blood. Three days later only a few scattered Rh-positive cell clumps were found, and on the 4th day after transfusion no Rh-positive cells could be detected. This case is of special interest in that no prior transfusion had been given, so that previous iso-immunization seems to have played no part in this phenomenon.

Case 6.—In an advanced unit two days before admission this patient had received 500 c.cm. of Rh-positive blood. The Rh test showed visible agglutination and he was given 1,000 c.cm. of Group A Rh-positive blood. After three transfusions the haematocrit reading did not rise to the expected level, and in preparation for further transfusions it was noted that the Rh test gave less marked agglutination than before and that at least half of the red cells were unagglutinated. During the following month a total of 3,000 c.cm. of Group A Rh-negative blood was given. The patient had no untoward reactions and there was no evidence of haemolysis in his plasma or urine after any of the transfusions. Within 10 days the bulk of the Rh-positive cells were eliminated, but small clumps of Rh_1 and Rh_2 cells persisted. The patient was completely negative, being of the genotype rhrh.* Repeated tests for blocking and agglutinating antibodies were entirely negative until 53 days after the last Rh-positive transfusion. On this occasion the patient's serum was tested by Diamond's (Diamond and Abelson, 1945) technique. A drop of oxalated whole blood, Group O Rh-positive, was placed on a slide and a small drop of the patient's serum was mixed with it and allowed to stand at room temperature. Within five minutes a marked agglutination was visible on the slide. This finding was checked with the usual tube agglutination technique, and visible agglutination in dilutions of 1:2 with microscopical clumping at 1:4 could be demonstrated. No blocking antibody was found. Diamond's test, employed eight days before in this case, was negative.

---

* The Rh typing was carried out by Dr. R. R. Race.

Group II

This group of 4 patients (Cases 7 to 10) had received blood before admission, but Rh tests showed them to be negative although clumps of Rh-positive blood had been given.

In Case 7 a considerable number of Rh-positive cells were retained for 47 days; by the 54th day most were gone, and all Rh-positive cells had disappeared within 60 days of transfusion. In Case 8 a similar situation was found, with complete loss of Rh-positive cells within 58 days. In Case 9 Rh-positive cells disappeared within 28 days.

Case 10 did not, unfortunately, remain under observation very long. This patient had had 2,250 c.cm. of blood before admission. With the last transfusion, a note on the chart stated that owing to chills, fever, and urticaria the transfusion was stopped. On admission to this hospital 10 days later there was no icterus or impairment of renal function. The nature of this reaction was not established. Practically all Rh-positive cells had been eliminated and only a very few small Rh-positive cell clumps could be found 10 days after the last transfusion.

Group III

In the 8 cases comprising this group the Rh type of blood given before admission was not known, and since no Rh-positive cells were retained the findings were incomplete. Statistically the chances greatly favour Rh-positive blood having been administered to these patients, but owing to lack of data no conclusions are warranted in this group.

Discussion

The survival of transfused red blood cells is influenced by a number of factors. The age of the blood, the preserving solution, and conditions of storage are obviously important considerations. In this study the cases in Group I were given blood preserved in a disodium citrate–glucose solution*; the blood was kept at 4° C., and no blood stored over 14 days was used. On two occasions fresh whole blood in citrate solution was given to cases in Group I.

The blood used in transfusions before arrival at this hospital was stored under less favourable conditions. It is possible that some of this blood preserved in Alsever's solution, or in glucose–citrate mixture, would survive for 60 days under proper conditions. However, with varying temperatures and the considerable handling necessitated by conditions in advanced medical installations, serious impairment in the ability of such stored blood to survive for normal periods must be admitted. Also, in contrast to studies of cell survival in normal controls (Callendar, Powell, and Witts, 1945), the recipients in all the cases under consideration were seriously wounded men. All had received sulphonamides and penicillin; many had some degree of sepsis. Obviously such complicating factors would not enhance the survival of transfused red blood cells. Therefore the rapid elimination of transfused red cells in certain cases in Group II and Group III might be attributed to non-specific factors rather than a phenomenon related to Rh or any other antigen–antibody mechanism.

However, the blood administered at this Hospital to the cases in Group I was preserved and stored in a manner similar to blood which, in recent transfusion studies, survived satisfactorily for 60 days or more (Loutit, Mollison, and Young, 1943). For this reason observations on the survival of this blood are of considerable interest. In Cases 1, 2, 3, and 4 the transfused red cells were eliminated rapidly and the previous transfusions may have had a sensitizing effect in spite of the fact that no antibodies were detected.

Case 5 had been given plasma but no blood before admission to this hospital. Within 3 days following a transfusion of 500 c.cm. of Group O Rh-positive blood he had eliminated all Rh-positive cells. No reaction or evidence of haemolysis had developed. Dacie and Mollison (1943) observed a similar rapid elimination of Rh-positive cells in an Rh-negative recipient during experiments on the survival of transfused red cells. They also noted this phenomenon in Rh-positive individuals, and Mollison (personal communication) is of the opinion that certain recipients have a peculiar ability, unrelated to iso-immunization, of eliminating transfused red cells.

In this group of Rh-negative cases repeated attempts were made to detect antibodies for the Rh factor. However, in only one case (No. 6) were antibodies discovered. In this patient, 53 days after the last Rh-positive blood was given, good anti-Rh agglutinins were found. If repeated observations had been carried out over a longer period of time antibodies for the Rh factor might have been discovered in other cases. Almost at the end of these investigations the important work of Diamond became available (Diamond and Abelson, 1945). Diamond found that even weakly agglutinating anti-Rh sera and sera containing blocking antibodies, when mixed on a slide with concentrated Rh-positive red-cell suspensions, gave a rapid and definite macroscopic agglutination. At the time only 3 Rh-negative cases remained in the hospital, but one of these (Case 6) gave a markedly positive reaction by Diamond's method.

In addition to detectable antibodies there are other more occult factors concerned in the destruction of Rh-positive cells in Rh-negative recipients. Wiener (1945) has pointed out that the biologic test will at times reveal a haemolytic process in a sensitized individual which cannot be demonstrated by *in vitro* tests. It is quite probable that other as yet unrecognized humoral products of sensitization may be discovered. Furthermore, it is not unreasonable to suspect that the haemoclastic process may be activated by a combination of both humoral and reticulo-endothelial sensitization. This aspect of the problem needs further investigation.

From a practical standpoint, in advanced medical units in wartime the problem of Rh-incompatibility must be disregarded. In general hospitals and other fixed installations a blood bank with available Rh-negative blood should be maintained. All Rh-negative patients should receive Rh-negative blood; this is especially important if blood has been previously given or if there is a possibility that multiple transfusions will be necessary. Diamond, in an excellent review on the clinical aspects of the Rh factor, points out the danger of iso-immunization by repeated blood transfusions, especially in the treatment of war wounds. In Rh-negative patients given Rh-positive blood difficulty may be encountered in deciding whether the patient is actually Rh-positive or not. In this series of cases the first serum available was of low potency,† so that weak and moderately positive tests on retained Rh-positive cells resulted in cases being classified as Rh-positive. With strong anti-Rh serum typical pictures of good clumps of Rh-positive cells surrounded by unagglutinated Rh-negative cells will usually indicate the true situation. In cases with retained Rh-positive cells further and more serious sensitization should be avoided by the administration of only Rh-negative blood if more transfusions are necessary.

Aside from the possibility of immediate or remote reactions, the evidence in the cases described above indicates that the transfusion of Rh-positive blood to Rh-negative individuals is inefficient because of the rapid elimination of the transfused red cells in many cases.

Summary and Conclusions

In a series of wounded soldiers investigated after transfusion of whole blood there was evidence of abnormally rapid elimination of transfused Rh-positive red cells from the circulation of some Rh-negative recipients.

While demonstrable antibodies were found in only one case, it is quite possible that iso-immunization and latent sensitization occurred in others of this group.

The mechanism of rapid loss of Rh-positive red cells from Rh-negative recipients is obscure. Various extrinsic factors may have influenced this phenomenon in certain cases in this series, or some as yet undetected antibody may play a part in this haemolytic process. The possibility that an activated reticulo-endothelial system (or other cellular agency) may be involved in the rapid elimination of Rh-positive cells deserves further study.

From the practical standpoint, Rh-negative individuals should be transfused with Rh-negative blood. While Rh iso-immunization may present few serious immediate reactions, any possibility of Rh sensitization should be avoided.

---

† This serum could not be refrigerated in transit, and lost its potency.

I am grateful for the unfailing kindness, assistance, and advice of Dr. R. R. Race and the late Dr. G. L. Taylor, of the Galton Laboratory, Serum Unit, Department of Pathology, Cambridge University. Thanks are due also to the members of the staff and the laboratory personnel of the 163rd (U.S.) General Hospital for their co-operation and help in this study.

ASYMPTOMATIC KALA-AZAR IN SOLDIERS FROM OVER-SEAS

BY

T. G. ARMSTRONG, M.D., M.R.C.P.

Late Lieut.-Col., R.A.M.C.; Officer in Charge of a Medical Division in a Military Hospital

The object of this note is to draw attention to the ease with which kala-azar may be overlooked in patients who make no spontaneous complaints. Two cases are described; both occurred in British troops who had served on the Mediterranean littoral. The first patient was seen in Italy and the second in England 20 months after his return from North Africa. Both, when pressed, admitted minor symptoms of several months' duration: these they had considered too trivial to warrant attendance on sick parade.

Classical kala-azar presents usually as a high swinging pyrexia, with periods of remission, and with marked toxaemia and sweating during the pyrexial periods. In both the cases reported here the fever was either slight or trivial, and toxaemia was absent.

Case I

Pte. H., aged 20. This man served in North Africa from Nov., 1942, to Nov., 1943. His disease probably originated in North Africa, for on arrival in Italy in Nov., 1942, he was stationed in the dock areas of Salerno and Naples, where kala-azar is not likely to be encountered. In May, 1944, he was ordered to report sick by his section sergeant, and was admitted to hospital. On direct questioning he admitted to a slow onset of general malaise, loss of weight, lassitude, and easy fatigability for the past 5 months. During this time he had continued to discharge his normal duties.

On examination he was thin and anaemic; and was found to be running an intermittent low-grade pyrexia up to 99° F. There were no abnormal signs in the heart or the lungs. The spleen was soft, was very difficult to feel, and was enlarged to three or four fingerbreadths below the costal margin. He was seen by several medical officers and specialists, who expressed doubt as to the splenic enlargement owing to its extreme softness and the absence of a definite edge. It was not until three or four weeks after his admission that the spleen was unreservedly accepted as being enlarged. The liver was normal in size. On the basis of the presenting clinical findings, and in the absence of a definite splenic enlargement, he was at first thought to be suffering from pulmonary tuberculosis; this was excluded by radiography.

The results of investigations were as follows. Many malaria films were negative. May 13: R.B.C., 3,120,000 per c.mm.; Hb, 59%; W.B.C., 4,850 per c.mm. (polymorphs 34%, lymphocytes 53%, monocytes 9%, eosinophils 4%); B.S.R., 58 mm. in 1 hour. May 26: W.B.C., 2,160 per c.mm. (polymorphs 24%, monocytes 5%, lymphocytes 70%, eosinophils 1%). Formol-gel test, negative. June 9: At this point the splenic enlargement was accepted as genuine, and in view of the marked leucopenia and granulopenia a marrow puncture was performed. Leishman-Donovan bodies were found in moderate numbers in the bone marrow. An inguinal gland was punctured but showed no parasites in the stained film.

The patient was treated with stilbamidine (diamidinostilbene), and made a slow but uneventful recovery.

Case II

Gnr. B., aged 25. This soldier served in North Africa from Jan., 1943, to Jan., 1944, when he was invalided to the United Kingdom with a severe attack of diphtheritic polyneuritis. He recovered completely and was returned to duty, remaining in England until the onset of his present illness. In Sept., 1944, he was admitted to hospital with an anxiety state following the flying-bomb attacks, and says that he was given a full physical examination at this time. After his return to duty he continued his work for nearly a year, and in Sept., 1945, came up for routine medical examination before demobilization. He was found to have a very large spleen and was admitted to hospital for investigation.

On admission on Sept. 23 he made no spontaneous complaints, but on direct questioning admitted to some dyspnoea on exertion for about 12 months, and had noticed that his belly had been increasing in size for about 9 months. He was unaware of any pyrexia, but had had occasional shivering attacks. He did not believe that he had become thinner. He denied ever having suffered from malaria.

On examination he was pale and thin. His complexion was sallow, and there was a slight brownish pigmentation of the anterior axillary folds. His temperature chart showed a nightly rise to 100°, with an occasional double crisis during a 24-hour period. There was a mild tachycardia, the pulse rate varying between 90 and 100. Sweating was not marked. The tongue was clean and moist. The chest showed dullness and diminished air entry at the left base owing to the enormous size of his spleen, but the lungs and heart were otherwise clear. The abdomen was tense and showed on its surface a number of dilated veins. The spleen extended well below the umbilicus and just crossed the midline. It was hard but not tender. The liver was almost certainly enlarged to two to three fingerbreadths below the costal margin, but it was covered with a resonant layer of colon, and neither an edge could be felt nor dullness to percussion be demonstrated. The lymph glands were normal in size and consistency.

Investigations resulted as follows: R.B.C., 3,120,000 per c.mm.; Hb, 55%; W.B.C., 1,400 per c.mm. (polymorphs 38%, monocytes 5%, lymphocytes 57%). Marrow puncture showed many Leishman-Donovan bodies. Ring forms of *Plasmodium vivax* were also seen. Gland puncture: Leishman-Donovan bodies were also easily found in smears made from the juice extracted by puncture from an apparently normal inguinal lymph gland. Formol-gel test, strongly positive.

The patient is at present being treated with stilbamidine.

Discussion

Though a rare complaint in British troops even on the shores of the Mediterranean, where the disease is endemic, kala-azar will certainly be seen for a time in England in troops who have returned from over-seas. In such persons it is not likely to occur very commonly, but it may well compare with the rarer blood diseases in frequency of appearance. If the mind of the physician is not attuned to the possibility of its appearance kala-azar may well be wrongly labelled and treatment withheld, with serious results.

The differential diagnosis in the slightly atypical forms recorded here should not be difficult. At first sight they may resemble pleurisy with effusion or phthisis. When the spleen is found, chronic malaria offers itself as an obvious diagnosis. When blood films are negative the chronic leukaemias come into question. The characteristic leucopenia may then suggest an "aleukaemic phase" in a myelocytic leukaemia, or perhaps some disease allied to the ill-defined Banti syndromes and splenic anaemias. In such cases sternal-marrow films are almost certain to be made; but the diagnosis may be missed even then, for the Leishman-Donovan bodies may be overlooked if the pathologist is not on the watch for them and has not been specially briefed by the clinician. They are often scanty in the bone marrow and may require a long search. If the bone-marrow films are negative it is always worth while to examine the juice obtained from the inguinal glands by puncture with a hypodermic needle. This should be done even if the glands are normal in size.

Summary

Two well-advanced cases of kala-azar with only slight fever and toxaemia are described.

The differential diagnosis, in relation to practical medicine in England, has been very briefly discussed.

It is stressed that further cases will occasionally be seen. A special watch should be kept for them.

S. Ben-Asher (*Ann. intern. Med.*, 1945, **23**, 431) records the case of a woman, aged 43, with mitral stenosis and auricular fibrillation in which an embolus in the right kidney resulted in rise of the arterial pressure. The blood pressure returned to normal with the disappearance of symptoms of renal infarction.

FOUR CASES OF RUSSELL'S VIPER BITE

BY

P. H. WYON, M.B.

Major, R.A.M.C.; Mobile Surgical Unit

Rarely has one a chance to see a number of snake-bite cases over a short period. These four cases were selected from 12 which occurred within a fortnight, in the same locality in Central Burma at the beginning of the Monsoon, the time when Russell's viper is known to be most active. The distribution of this snake is over India, Burma, Malaya, and the Dutch East Indies; and as its bite is curable if promptly treated, these cases have considerable topical interest.

Treatment Adopted

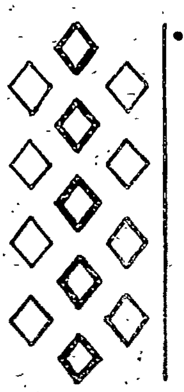
The 12 cases were treated according to a routine. If not already in place, a tight tourniquet was quickly applied to the limb above the bite. Antivenene was administered intravenously at once. Most authorities agree that it should be given in large doses—as much as 30 c.cm. initially, followed by 10 c.cm. hourly up to a total of 80 or 100 c.cm.

The patient is next anaesthetized with pentothal, and an incision at least 3 in. long made, if practicable, in the line of the bite. It was carried down to, but not through, the deep fascia, unless there was evidence that this structure had been penetrated. The incision was made for the purpose of diagnosis and of treatment. In each of the four cases of Russell's viper bite the typical purple-to-black discoloration was present. These cases were then treated drastically by venesection from the affected limb and by retaining a venous tourniquet for as long as 18 hours. By releasing the tight tourniquet regularly, intermittent venesection was achieved. If necessary the patient was transfused with whole blood. The only method of saving life is by preventing the venom from reaching the general circulation. Antivenene alone does not save life.

The other eight cases of this series all showed definite punctures. In three the snakes were available, and were identified as almost certainly non-poisonous. However, each patient was incised at once: some showed no reaction at all; others, clear oedema only. As a safeguard a venous tourniquet was retained some hours and antivenene was administered. No case showed any generalized reaction.

Description

In each of the four cases of this series the snake was identified beyond doubt as a Russell's viper. The largest was sent to the district laboratory for confirmation. This snake was 4 ft. 6 in. in length, and fully 2½ in. in diameter from the "shoulder to the vent," where it rapidly tapered. The Russell's viper is identified by the triple row of diamonds, coloured black to dark brown, down the back. The centre row is the most strongly marked. The dorsal scales are small and equal in size; the ventral scales go right across the belly. In the upper jaw are the two backward-curving fangs in the "canine" position. In the large specimens the fangs are 3/4 in. long. It is of interest that a small Russell's viper 2 ft. 6 in. long, and no thicker than a thumb, caused severe symptoms in one case.



Case I

An Indian pioneer, aged 30, bitten at 12.30 a.m. on May 18, 1945, by a Russell's viper 4 ft. long. No notes on field card except that he was given 10 c.cm. of antivenene soon after the bite. The case was first seen by the surgeon at 9 a.m. the same day. The whole of the right forearm was tensely swollen and tender; on the anterior surface of the wrist two punctures were surrounded by a dark discoloured zone. Pitting oedema extended for some inches above the elbow. Pulse 100; volume fair. A tight tourniquet was applied to the upper arm. 10 c.cm. of antivenene (conc.) was given I.V., and repeated twice at half-hourly intervals. Pentothal at 10 a.m. Multiple incisions on anterior surface of forearm, releasing great tension. Subcutaneous tissues at wrist were black and not bleeding; at elbow, purple and bleeding only slightly. Deep fascia was incised—muscle of normal colour and not under tension. A venous tight tourniquet was retained for six hours thereafter. At 2 p.m., pulse 140, barely perceptible at wrist, but B.P. 140/80. At 8 p.m., pulse 150–160; pulseless at wrist; vomiting. I.V. glucose-saline given (10 c.cm. antivenene to pint)—3 pints in 7 hours. At 11 p.m., mentally clear; sat up spontaneously; no pulse at wrist; swelling had spread to pectoral region. The patient died at 5 a.m. next day. He was mentally clear to the last. No necropsy.

Case II

A British gunner, aged 25, was bitten just after midnight of May 19, 1945, by a Russell's viper 4 ft. 6 in. long. A tight tourniquet was applied to the upper arm within a few minutes; two 1/4-in. incisions were made through the bites. 10 c.cm. antivenene (conc.) given I.V. Admitted to surgical ward at 1 a.m. Very tender round site of bite on the left thenar eminence. Swelling extended 2 in. upwards from punctures, which were 3/4 in. apart. A vein on the dorsum of the wrist felt quite firm, as if thrombosed. Pulse 100; patient was alarmed, as the snake was "as thick as your wrist." 10 c.cm. antivenene (conc.) given I.V., and repeated 1/2-hourly for 4 more doses. 1.30 a.m.:—Pentothal; 3-in.-long incisions made through each puncture. Subcutaneous tissues and muscles of thenar eminence found to be black to a depth of 3/4 in. Dorsum of wrist incised and the vein opened, but bled freely when tourniquet was maintained at venous pressure. Venesection 1/2 pint from this vein. Later it was found that this blood, and also the blood from the opposite arm (taken for cross-matching), did not clot even after 10 hours. It sedimented like citrated blood; the supernatant plasma showed very slight haemolysis in the lower part. A tight tourniquet (Esmarch's) was then applied at the elbow and released for 5 minutes every half-hour. As a venous tight rubber tourniquet below this was never released intermittent venesection was achieved. The venous tourniquet was retained for 18 hours. At 11 a.m. the patient was moderately exsanguinated. Pulse 120; volume satisfactory. One pint of Group O (IV) blood was transfused, followed by I.V. saline drip (10 c.cm. conc. antivenene to pint), 2 pints in 5 hours, followed by a second pint of blood. 10 p.m.:—Severe oedema of forearm below tourniquet; no spread of discoloration; both tourniquets removed; pulse 100; condition satisfactory; 20 c.cm. antivenene given I.V.

May 21.—Condition improving; oedema of forearm subsiding; no signs of general absorption of venom.

May 22.—Pentothal. The three gaping wounds were found to be very clean; they were sutured. Parenteral penicillin given for 5 days.

May 30.—Sutures removed; 2 wounds had healed 100%, one 90%. Severe general debility, in excess of that expected from his anaemia. Though a robust and very well built man, he was unable to walk.

June 1.—Felt better; sat up; hand and finger movements full range. Evacuated to base; long convalescence recommended.

Case III

Indian sepoy, aged 35, bitten at 1 a.m. on May 26, 1945, by a Russell's viper 2 ft. 6 in. long. No notes on card. Brought to surgical unit at 8 a.m. Two punctures present on anterior surface of right ankle. Oedema of whole right foot and ankle. 10 a.m.:—Pentothal. Incision 4 in. long through punctures. Tissue 1/2 in. by 1/2 in. at site of punctures was black, with clear oedema round. Venous tight tourniquet retained 18 hours. This caused mild venesection. 10 c.cm. antivenene (conc.) given I.V., and every hour for 4 hours. *May 27:*—No evidence of general absorption of venom. Quick recovery occurred. Presumably little venom had been injected. The incisions healed in 14 days.

Case IV

Indian tailor (military), aged 25, bitten at 6 a.m. on May 26, 1945, by a Russell's viper 2 ft. 6 in. long. Admitted to surgical unit at 10 p.m. Two punctures seen 3 in. below elbow; tender; forearm and hand oedematous. He walked to hospital. 11 p.m.:—Pentothal. Incision through the punctures. Two small black areas seen, surrounded by oedematous subcutaneous tissues. 10 c.cm. conc. antivenene given I.V., and repeated 3 times hourly. Venous tourniquet applied above elbow; slow venesection occurred.

May 27.—Condition deteriorating; pulse 120, barely perceptible at wrist, but B.P. normal (sounds very faint). Mentally clear; restless; vomiting. Venous tourniquet retained 24 hours, but he did not appear exsanguinated. 12 noon:—Two pints whole blood transfused, followed by I.V. drip, with antivenene 10 c.cm. to pint. Pulse improved slightly; urine contained albuminous clots.

May 28.—Pulse 120; poor volume. Abdomen distended; meteorism; vomiting; diarrhoea. The condition resembled paralytic ileus. I.V. saline continued. Continuous gastric suction started; green fluid aspirated.

May 29.—Pulse 110. Abdomen still tumid and resonant. I.V. saline and antivenene continued; gastric suction.

May 30.—Chest: moist sounds; abdomen rather less distended. Saline and suction discontinued. Later no vomiting; drinking well. Pulse now improved.

May 31.—Chest clear; asking for food. Recovery. Incision healed in 10 days.

Points of Interest

The most striking points are: (1) The bites are tender from the first; the swelling spreads steadily. (2) On incision at the site of puncture the subcutaneous tissues are black, due to extravasated and altered blood and later to necrosis. In the fatal case this discoloration spread the full length of the forearm. (3) In two cases the pulse steadily deteriorated. After 12 to 24 hours it was almost imperceptible, yet repeated B.P. readings were normal.

A colleague told me of two fatal cases of Russell's viper bite which occurred in the same area. The patients were bitten on the neck and thorax respectively. In these and in Case I it was noticed that (*a*) the swelling spread steadily and widely; tissues round the punctures became discoloured. (*b*) Patients remained conscious to the last, though the wrist pulse had been imperceptible for many hours. (*c*) Death occurred in 30 to 36 hours.

Three features appear difficult to explain: (i) In Case II a vein which appeared to be thrombosed 1 hour after the bite was found half an hour later to bleed freely. (ii) The blood in Case II did not clot; yet, therapeutically, snake venom is used to aid clotting. (iii) A condition in Case IV resembling paralytic ileus.

Acton and Knowles (1921), however, state that Russell's viper venom contains three active principles—thrombase, haemorrhagin, and an unspecified proteolytic ferment. *Thrombase*, if injected into a vein, as is common in small animals, causes rapid thrombosis and death. In man this is rare. The presence of thrombase in the subcutaneous tissues causes local necrosis. *Haemorrhagin* produces lysis of the cells of the capillary walls; hence the local extravasation at the puncture sites, as seen in each of the four cases presented. This extravasation accounts for the oozing of blood from the punctures—said to be a diagnostic feature. If haemorrhagin reaches the general circulation it may cause widespread petechial haemorrhages in such organs as brain, kidneys, stomach, intestine, or lungs. Thus signs consisting of fits, depression, and paralysis of vital centres, albuminuria, haematemesis, and haemoptysis occur. Haemorrhages into the wall of the gut account for the symptoms resembling paralytic ileus in Case IV. The damage to the kidneys may account for the maintained blood pressure in two cases in spite of very poor wrist pulse, and also the large albuminous clots in the urine.

Acton and Knowles also state that the early thrombi caused by thrombase are later dissolved by the proteolytic ferment. They do not specify the agent, but say that it is known that thrombi disappear, as in Case II. This agent, acting on the fibrinogen, prevents clotting of systemic blood, as observed in Case II. Calmette (1908), the first to prepare antivenene, stresses the proteolytic action of viper venom.

Treatment

Many cases of Russell's viper bite are amenable to treatment if it is applied early enough; whereas bites of cobra and krait are very rapidly fatal. Hamilton Fairley (1934) advises immediate ligation, free incision, local venesection, and mechanical suction. Local injection of gold chloride and potassium permanganate causes necrosis, and the value of these substances is doubtful. Amputation he considers unjustifiable for Russell's viper bite (as do Acton and Knowles). In this connexion it is interesting that Himalayan tribesmen immediately cut off a digit if it is bitten by a snake. Fairley casts doubt on the efficacy of antivenene, as it is unlikely that the specific antivenene for the snake concerned is available; its potency may well have expired; and there are valueless brands on the market. Stitt (1942) recommends a total dosage of 100 to 300 c.cm. I.V. or I.M.

Transfusion of whole blood is necessary if much is lost by venesection. I cannot find any reference to the prolonged use of a venous tourniquet, but it seemed to be of value in my cases.

Summary

Four cases of Russell's viper bite are presented. The known properties of the venom are discussed.

The diagnostic symptoms and signs are: persistent pain and tenderness, oozing from the punctures, spreading swelling, and on incision a "red-currant jelly" appearance.

Modern ideas on treatment are summarized.

BLINDNESS FOLLOWING HAEMATEMESIS

BY

JAMES BLACK, M.D., F.R.F.P.S.

Assistant Physician (Temporary), Sunderland Royal Infirmary

Though long recognized, blindness following haematemesis is rare enough to warrant publication of a further example. Gowers (1904) discussed this complication at length and reviewed the literature to that date. More recently Whiting (1929) described three cases, and Rugg-Gunn (1937–8) reported the case of a man of 47 who, after a severe haematemesis, became completely and permanently blind. Rugg-Gunn also cited a case in which the blindness was not permanent. Bamford and Barber (1940) reported the case of a man of 46 who had two haematemeses at an interval of three days; a gradual contraction of the fields of vision five days after the first bleeding heralded the development of complete and permanent blindness of both eyes. Robertson (1941) described the development of sudden and complete loss of vision in the left eye on the third day after a haematemesis; next morning there was only a glimmer of vision in the right eye. Permanent and complete blindness resulted.

There is no agreement on the pathogenesis, and the retinal appearances differ from case to case. The time and mode of onset vary, as do the degree and duration of blindness. Chevallereau (1903) stated that the blindness is more often bilateral. Fries, quoted by Gowers (1904), found that it was bilateral in 90% of cases and that the time of onset varied, 26% losing their vision at once, 19% within 12 hours, 33% between 12 hours and 18 days, and 22% thereafter. The defect of vision may be a diminution of central vision, paracentral scotomata, sector field defects, or concentric contraction of the fields of vision, while in other cases there is sudden and complete loss of sight. Once vision is lost it appears to be permanent in most instances. Coyon *et al.* (1927) stated that the condition is invariably followed by complete optic atrophy. Sweet (1903), however, recorded a case in which there was slight improvement. One of Whiting's cases showed very slight recovery, and Rugg-Gunn reported recovery where the blindness had been originally complete.

The fundal appearance varies from case to case. In his case Gowers found the disk atrophied and greyish white, the arteries narrowed, and the veins small. There was some new tissue around the vessels in the disk. He stated, however, that the ophthalmoscopic appearances in other recorded cases varied from slight to intense inflammatory change; in the more intense cases there was neuroretinitis with haemorrhages. Rugg-Gunn's case showed papilloedema of both disks and narrowing of the retinal arteries. Whiting noted pallor of the disks with blurring of the edges, small patches of exudate, but no haemorrhages.

Case Report

The case here described, that of a coal-miner aged 53, was admitted to hospital on Aug. 18, 1945, and gave the following history.

During the preceding three weeks he had suffered from lassitude, anorexia, and occasional dull epigastric pain after food. Prior to this he had experienced no digestive upset, but had occasionally seen a streak of blood in the motion. This slight bleeding he had attributed to haemorrhoids. His sight had always been good and he was not subject to headaches. On Aug. 12 he had noticed a trace of blood in his motion. On the 13th, while resting at home in a chair, he suddenly collapsed and lost consciousness for some 10 minutes. On recovering from the faint he vomited a "considerable quantity" of bright-red blood—probably more than a pint. Soon afterwards he passed a tarry motion which was followed by another haematemesis. On the evening of Aug. 15 he felt fairly comfortable and managed to glance through a newspaper. On the morning of Aug. 16 he woke to find that he was totally blind in the left eye and appreciated only hand movements with the right eye. Within a further 15 minutes the right eye also was totally blind. There was no further haemorrhage.

On admission to hospital he was completely blind in both eyes. His mental condition was clear. There was marked pallor of the skin and mucous membranes. Pulse was 80 a minute, regular, and of fair volume. There was no thickening of the radial vessels. B.P. was 135/80 and Hess's test was negative. Haemoglobin (Sahli) was 25%. There was some tenderness in the right hypochondrium but no rigidity. The liver and spleen were not enlarged. The eye-movements were full. Ophthalmoscopic examination showed disks which were hyperaemic and somewhat swollen (2D). The disk-margins were ill defined, the arteries markedly constricted, and the veins dilated. There was no nipping of veins. Two streaky haemorrhages were seen in the right fundus near the disk margin at 2 o'clock and 7 o'clock. A similar haemorrhage was noted at 3 o'clock near the disk margin in the left eye. No exudates were observed. The pupils were widely dilated, circular, and fixed. The spinal reflexes were sluggish. The cerebrospinal fluid was under 200 mm. pressure; there was no blood present and no cellular increase.

1¾ pints of Group O blood was administered by intravenous drip, and iron was given in full doses. Three days after admission the haemoglobin had risen to 46%. Red cells numbered 2,290,000/c.mm., white cells 3,800/c.mm., platelets 200,000/c.mm. There was anisocytosis and poikilocytosis of the red cells, and the differential white count was within normal limits. The blood urea was 29 mg./100 c.cm. Twelve days after admission the haemoglobin was 70%, 27 days after 85%, and 31 days after 89%. *X*-ray examination by barium meal 34 days after admission showed a deformity of the duodenal cap.

The patient was discharged after 38 days feeling well, with a good appetite, and without pain. He was still completely blind in both eyes. The pupils were central, circular, equal, and of moderate size, but did not react to light. There was now obvious optic atrophy, the haemorrhages had disappeared, and the arteries were still narrowed.

Discussion

Various theories have been advanced to account for the blindness. Samelsohn, quoted by Gowers (1904), considered that the nervous connexion between stomach and corpora quadrigemina afforded the best explanation, it having been noted that the disease or injury of the corpora could give rise to haematemesis. Goerlitz (1920) examined an eye pathologically 10 days after the onset of blindness following haematemesis; the main changes found were an intense oedema of the disks and oedema of the retina, these changes resembling those found in intoxication amblyopia such as is caused by methyl alcohol. Whiting (1929) favours the hypothesis that toxaemia renders the ganglion cells more sensitive to blood deprivation and that sudden death of the ganglion cells and their fibres is responsible. Fisher (1929) suggested that exudation of fluid in the nerve sheaths might be responsible. Wolff, quoted by Rugg-Gunn (1937-8), suggested that diminished oxygen supply might lead to spasm of the arterial walls and so be the cause of the blindness.

In the present case one of the most striking features was the marked contraction of the retinal arteries. And whereas a raised blood urea might have been expected the level was unusually low—viz., 29 mg./100 c.cm. Whether this low urea level is of any significance is open to discussion.

Summary

The literature on blindness following gastro-intestinal haemorrhage is briefly reviewed.

Details of a case showing this rare complication are given.

The present case gave a history of having had small repeated blood losses, possibly from haemorrhoids, before the haematemesis.

There was marked contraction of the retinal arteries.

By a wider appreciation of the existence of this unusual complication of haemorrhage and adoption of routine inspection of the fundi for early changes this catastrophe might be avoided. A blood transfusion, given early, may halt these changes and be a sight-saving measure. Once vision has gone there is little likelihood of response to any form of treatment.

Medical Memoranda

Anaesthesia and Blood Transfusion in 14 Cases of Traumatic Aneurysm

Anaesthesia and blood transfusion for cases of aneurysm present problems to be met with only in peacetime when working in conjunction with a surgeon doing blood-vessel surgery. This military hospital has had 14 cases of aneurysm over a period of 16 weeks. The literature available reveals very little on this subject. The cases, being battle casualties, presented the text-book description of a traumatic false aneurysm, with the exception of the so-called varicose arteriovenous type. When removal of this particular type was attempted it was found to have so many ramifications that blood loss was liable to be tremendous.

All the subjects were brought to the operating theatre in good condition, the average length of time between injury and operation being approximately 4 weeks, giving the opportunity for pre-operative blood transfusions if necessary. No case was operated on until the blood pressure was within normal limits. The premedication used was morphine 1/4 gr. with hyoscine 1/100 gr., while the anaesthetic in 8 of the 14 cases was pentothal 0.5 g., N_2O, vinesthene, and oxygen, and usually but not always ether in conjunction with a (home-made) CO_2 absorber. The remaining cases were given pentothal 0.3 g. and ether through an Oxford vaporizer with the addition of oxygen. Care was always taken to give a liberal quantity of oxygen, particularly when the transfusion could not keep pace with the blood loss. The sites of the aneurysm were carotid, subclavian, brachial, popliteal, and femoral—this warranting the use of intratracheal intubation in the first four types. The average length of time of all operations was just over three hours.

It was found that planning and preparation for a sudden and tremendous loss of blood were needed in all cases, for it could never be determined beforehand which case more than another was likely to have a severe haemorrhage. Before starting any of the operations the local blood bank was asked to supply 5 pints of fresh blood ready for immediate use. As soon as the anaesthetic had reached the third stage and before beginning the operation a needle was inserted and a slow drip started. If there was only the small blood loss to be expected at any operation the transfusion was allowed to drip at 60 a minute, but the transfusion, in any minor or major loss, was ready for immediate use as a stream, even under positive pressure. In two of the cases the loss was so great that a second transfusion had to be set up in order to maintain blood volume. As more experience was gained it was decided to try autotransfusions, but in the latter cases there was no justification for the attempt. Team-work was absolutely essential—as, for example, in two cases when the supply of blood was exhausted, donors having to be called for and bled.

There were 2 deaths. The first of these occurred in a case of popliteal aneurysm four hours after operation, when the patient had recovered consciousness. The blood loss had not been heavy, and had been replaced with one pint of the same group. Unfortunately there was no necropsy. It was thought that death was due to pulmonary embolism. The second death, in a case of subclavian aneurysm, occurred on the table, after 1¾ hours' operating time, from a sudden uncontrollable haemorrhage with which no transfusion could have kept pace. Up to the time of this incident the condition of the patient had been quite satisfactory.

The following successful extreme case indicates the difficulty of the surgeon and the anaesthetist, and shows not only the amount of blood a man can lose, and have replaced, but also the amount he may need if a favourable result is to be obtained.

ILLUSTRATIVE CASE

On the morning of Aug. 14, 1944, Major F. was operated on for a femoral aneurysm of the arteriovenous type. After 3½ hours' operating the procedure was stopped at the request of the anaesthetist in spite of the fact that the haemorrhage was not under control. The wound was packed. The patient had been given 4¼ pints of blood and half a pint of plasma. The same day, 8 hours later, his condition having improved, he was again taken to the theatre, and this time 9½ pints of blood were given with half a pint of plasma. The operation was again stopped at the request of the anaesthetist, after 4½ hours. The wound was still bleeding, and was packed as before. Five days later he was returned to the theatre, and this time the operation was successfully concluded after 4 hours and 40 minutes, the patient having received 8 pints of blood and half a pint of plasma. The plasma was used only to tide over the intervals between the obtaining of whole blood. The total operation time was 12 hours 40 minutes, while the total of transfused material was

21¼ pints of blood and 1¼ pints of plasma, given over a period of 6 days. One is tempted to ask if this is a record for the amount of blood given over such a short period. The anaesthetic used was pentothal 0.5 g., N_2O, and oxygen, with an absorber. The patient's condition 10 weeks after operation can be regarded as satisfactory. In the first two operations both Groups A (II) and O (IV) were used in about the proportion of 2 to 1, while in the last operation A only was given.

The patient's blood picture at the present time shows the following: R.B.C., 4,200,000; Hb, 71% (Sahli); W.B.C., 6,800 (polymorphs 59%, lymphocytes 28%, monocytes 12%, eosinophils 1%).

COMMENT

Anaesthesia for cases of aneurysm presents no unusual difficulties, but a liberal quantity of oxygen is indicated, particularly when the blood loss is heavy. Planning and preparation for a large blood loss in these cases was always necessary. Transfusion was given to all cases in order to be immediately ready for any emergency. In two cases two transfusions were set up at the same time in the one patient. With all precautions a transfusion may not be able to keep pace with blood loss.

I wish to thank Col. J. Bruce, consulting surgeon, for permission to publish this article.

I. SCHALIT, M.B., B.S.;
Major, R.A.M.C.; Recognized Specialist in Anaesthetics.

Local Penicillin in Purulent Pericarditis

The following case of acute purulent pericarditis was treated by direct infusion of penicillin in Ringer's solution after surgical drainage. Two complications—pleural effusion and infection of an inadequately removed rib cartilage—arose during treatment.

CASE REPORT

The patient is a full Samoan, aged 29, and a local resident. He was admitted on Dec. 16, 1944, with fever, pains in the head and chest for 5 days, a cough for 7 days, and an abscess on the left leg for 7 days. The abscess had been discharging for 2 days before admission. His previous history was a pleural effusion, for which he had been treated in hospital 7 years ago. The diagnosis was toxaemia secondary to the abscess of the leg. A bacteriaemia was suspected, but no growth occurred after 5 days' incubation.

On the night of admission his temperature rose from 103.8° to 105°, but dropped the following day to 100°, thereafter fluctuating between 102° and 99° until the second day after operation. His white cell count was 12,650. He was given 2 g. of sulphapyridine on admission and 1 g. six-hourly for three days. At this time sulphadiazine was substituted, and he received a course of 33 g. in 9 days. The response was poor, and he was given 6 g. of sulphathiazole in two days without any benefit. Two weeks after admission his white cell count had risen to 18,100 and the blood cultures were still negative.

20th Day.—A pericardial rub was audible and fine rales were heard in the bases of both lungs. Intravenous penicillin was started (225,000 units in 48 hours); the temperature, pulse, and clinical condition remained unchanged.

28th Day.—Red cells, 3,600,000; Hb, 76%; C.I., 1.05. White cells, 9,800 (polymorphs 62%, lymphocytes 24%). The apex beat was now in the midaxillary line and the right border was 2 in. beyond the right sternal border at the 5th intercostal space. The neck veins were prominent, and the patient was in great respiratory distress.

32nd Day.—I was called in consultation. At this time his precordial dullness was continuous on the left from the 2nd interspace in the midclavicular line to the midaxillary line at the 6th space. The right border was at the midclavicular line in the 6th space. Heart sounds were not audible. Breath sounds were absent in the left lower chest, and coarse rales were heard throughout the remaining areas of the chest. The pericardium was aspirated through the 5th intercostal space, 30 c.cm. of blood-stained semipurulent fluid being removed. Vision was almost absent in the left eye and blurred in the right. In preparation for surgical intervention a blood examination was made, with the following results: Group O; red cells, 4,400,000; Hb, 87%; C.I., 0.98; while cells, 5,200 (polymorphs 66%, lymphocytes 18%); Schilling, left shift 3:1; sedimentation rate, 41 mm. in 1st hour; bleeding time, 3 min.; coagulation time, 4 min.; total serum protein, 7% (albumin 4.6%, globulin 2.1%); mean corpuscular haemoglobin concentration, 48%; culture sterile after 7 days' incubation.

35th Day.—I performed a pericardiotomy, using local analgesia, through a linear incision centred over the 5th and 6th rib cartilages. Two inches of the rib cartilages was removed. The intercostal bundles were incised in the line of the incision and sutured to the deep fascia. Two tie sutures were inserted into the pericardium and the incision made between. There was an immediate burst of effusion, projected 12 ft. Using the tie sutures to open and shut the incision, gradual decompression was effected. Two and a half pints of effusion was expressed by heart action. The tie sutures were then united to the skin to ensure patency. 20 c.cm. of penicillin (1,000 units per c.cm. in Ringer's) was instilled into the sac with a Dakin syringe, and a vaselined gauze dressing laid on the wound. The blood pressure at the start of the operation was 94/54: no appreciable change occurred during the operation. 500 c.cm. of whole blood was given during the procedure, followed by 1 litre of 5% glucose-saline at 36 drops a minute. B.P. readings were taken at 15-minute intervals for the next 8 hours, being uncertain of the origin of the blood in the effusion. The maximum reading was 138/80, and the minimum 94/50; after 6 hours it became constant at 108/62. The pulse during this time was a maximum of 134 and a minimum of 100 a minute. The effusion gave a heavy culture of pure *Staph. aureus*, sensitive to penicillin *in vitro* (38 mm. zone of inhibition).

Conspicuous relief of cardiac and respiratory distress was apparent 4 hours after operation. Twice-daily dressings were done, 10 c.cm. of the same concentration of penicillin being instilled each time, for five days.

2nd Post-operative Day.—Sulphadiazine was begun because of our limited supply of penicillin, a course of 24 g. being given in 13 days. From this time onwards the temperature fluctuated between 97 and 98.8° until March 18.

8th Post-operative Day.—B.P., 102/68; pulse, 90; respiration rate, 22. The apex beat was 4½ in. from the midline in the 5th intercostal space, all heart sounds clearly audible but still faint; moist sounds were heard in the pericardium. Blood examination showed: Red cells, 4,800,000; Hb, 90%; C.I., 0.92; sedimentation rate, 21 mm.; white cells, 6,500 (polymorphs 53%, lymphocytes 38%); Schilling, right shift 8:11.

By the 17th post-operative day the sinus had closed spontaneously, but some discomfort was felt. The sinus was opened, releasing about 30 c.cm. of penicillin-stained serous fluid with no active units. On the 19th post-operative day 10 c.cm. of similar fluid was aspirated: a guinea-pig test revealed nothing pathological. By the 21st post-operative day (Feb. 10) the precordial sinus had closed, and the patient progressed satisfactorily until the 45th post-operative day (March 5), when the wound became tender. On the 50th post-operative day (March 10) it broke down, and a semi-purulent discharge began. Four days later 1 pint of fluid, similar to that previously evacuated, was removed. Some pain and embarrassment were felt and aspiration was discontinued. On March 21 (61st post-operative day) gentle curettage was performed. On April 16 the patient was discharged to the out-patient department with a draining sinus. Two weeks later he was readmitted for removal of an infected cartilaginous tip of the 5th rib. By May 22 the wound had healed and the patient was discharged. The heart was then within normal limits and the chest clear and resonant throughout; B.P. 112/78. Eyes: both fundi clear; fields normal; left eye 6/12, right eye 6/18, Snellen.

There is as yet no clinical evidence of any pericardial adhesions, which will perhaps be found later, and I anticipate the follow-up with interest. The normal base-line temperature of Samoans is 97° F.

Apia, Western Samoa. MARSHALL M. GOWLAND, M.D., C.M.

A Very Large Granulosa-cell Tumour of the Ovary

The following case is of interest because of the unusually large size of the tumour.

CASE HISTORY

The patient, a woman of the Hausa tribe of Northern Nigeria, aged 35, was first seen in Sept., 1944, when she complained of gross enlargement of the abdomen. Two years and ten months previously she began to suffer from continuous uterine bleeding, with the passage of clots of blood. This lasted for ten months, and was followed by complete amenorrhoea for the two years up to the date of examination. The enlargement of the abdomen began two years ago and gradually increased throughout this time. Menstruation was normal before the onset of the condition. The patient was married at about 14 years of age (as is the practice of the Hausa people), and had three live children, the last 16 years old, and a miscarriage ten years ago. Since then she has had no further pregnancy.

On examination the patient was seen to be a thin woman with an abdomen larger than the average full-term pregnancy. The swelling was not uniform, but was more prominent in the hypogastrium and left iliac fossa. Per vaginam the lower pole of the tumour was felt through the posterior fornix. The position of the uterus could not be properly defined.

On Sept. 8, 1944, laparotomy was performed under open ether anaesthesia. The tumour was found to arise from the right ovary, and had a well-defined pedicle. Numerous omental adhesions were divided, the pedicle ligated and divided, and the tumour removed. The uterus was of normal size; the left ovary was atrophied as in a patient after the menopause. The abdomen was closed and the patient was given glucose-saline per rectum. Her recovery was straightforward. The tumour was found to weigh 20 lb. The greater part of it was solid—in some places necrotic. There was a cystic part about 6 in. across. Portions from the solid part of the tumour and from the wall of the cyst were examined microscopically by Dr. G. W. St. C. Ramsay, acting senior pathologist at the Medical Research Institute, Yaba, Nigeria, and he reported as follows.

"The specimen is a granulosa-cell tumour of the ovary. In the cystic part the tumour assumes a papillary form; elsewhere it is composed of solid masses of polyhedral cells with vesicular nuclei divided up by strands of rather hyaline connective tissue. The size of the tumour may possibly be a record. Ewing quotes one case weighing 10½ lb., or just about half the weight of this specimen."

The patient was seen again about three months after the operation and was then in good health.

I am greatly indebted to Dr. Ramsay for his report and for photomicrographs he prepared from the sections of the tumour.

Reviews

MEDICAL USES OF SOAP

Medical Uses of Soap: A Symposium. Edited by Morris Fishbein. (Pp. 182; illustrated. 18s.) London: J. B. Lippincott Company. 1945.

The skin is subjected to the action of soap more often than to that of any other definite chemical substance, and it is rather surprising, in view of its importance in cutaneous hygiene, that no authoritative publication on the medical uses of soap has hitherto appeared. The present volume will fill a gap. What is soap? If it is to be defined as a chemical compound, soap is any salt of those fatty acids that contain eight or more carbon atoms; but many of these salts do not possess the detergent qualities which characterize soap in the mind of the man in the street. On the other hand, there have lately been developed a number of substances which resemble soap in their detergent action but which do not conform to the chemical definition set out above. They are known as "surface active" agents. Among them are sulphated oils and sulphated alcohols and esters—these have been only recently introduced into commerce, but are becoming serious rivals of the orthodox chemical soaps. They have an importance in medicine, for, as is well known, many skins are sensitive to ordinary soap, and the new detergents do not irritate the skin in the same way that soap irritates it because they are non-alkaline, though of course they may irritate the skin in some other way. Up to now very few reports have been published of dermatosis resulting from their use. It appears, therefore, that these detergents have advantages for patients with very sensitive skins.

It is a curious thing to remember that soap as we know it is quite a modern invention. Although the word "soap" has been known since classical times, it seems that the Latin word *sapo* from which the modern English word is derived was not a detergent at all but something rather in the nature of a scent or perhaps a deodorant. The soaps made from the alkaline salts of the fatty acids (of which oleic acid, stearic acid, and palmitic acid are still the most generally used varieties) are a comparatively modern invention, and their commercial manufacture dates from the early days of the nineteenth century, while the marvellous developments and infinite specialization of different kinds of soap to suit special needs have been chiefly evolved during the last seventy or eighty years.

In the volume before us all the points of contact between medicine and the soap industry are thoroughly dealt with. There is a good summary of soap technology and the effects of soap on the normal skin and the diseased skin, of the evils that may result from its injudicious or excessive use, and of its contraindications. There are two sections which may be particularly commended to the study of dermatologists: one is on the effects of soap on the hair, and the other is on soap for shaving. Much of the article on "Soap for Shaving," by Dr. Hollander, is interesting because it supplies scientific reasons for everyday practice. It has long been known that thorough lathering of the face greatly facilitates shaving, and Dr. Hollander describes experiments which show that soap solution actually softens the hair to such an extent that, whereas dry hair is hardly stretchable at all, full saturation with water allows it to be stretched by as much as 50% of its original length. In accordance with current practice among those who shave—that is, practically the whole adult male population of civilized countries—his experiments also show that hot water and soap solution gives the best results. In one point only does he differ from the opinions of most people who practise the art of shaving, and that is when he says that a "dull" razor causes less trauma to the skin than a very sharp one; and that is a surprising conclusion. There is one precaution which he might have mentioned in dealing with tender skins, and that is the advisability of going not more than once over the surface to be shaved and dispensing with a really close shave, which can only be obtained by going over twice.

It is not possible to give an abstract of this interesting book within the limits of a short review, but we do recommend it cordially, not only to the medical and nursing professions at large, but also to trichologists and practitioners of the cosmetic arts. There are numerous apposite and well-reproduced illustrations.

BEVERIDGE REPORT AND WHITE PAPER

Britain's Way to Social Security. By François Lafitte. (Pp. 110. 6s.) London: Pilot Press. 1945.

The Beveridge literature continues to grow, and any contribution to it which deals with it from a fresh point of view can be welcomed. This book is by a firm believer in the Beveridge plan, and he has thought it useful to make an objective comparison of the Beveridge report with the modifications of the White Paper.

The main part of the book seems to have been written before the General Election. The author is, however, not disturbed by the new developments, because he believes that the electors wanted "social security" whichever side won. He does not hesitate to say sometimes that the proposals of the White Paper are better than those of the report, but believes that those of the White Paper are, generally speaking, less favourable to the citizen than the original ones. The value of the book is greatly enhanced by a section which gives a concise and very clear story of the inception and reception of the report, preceded by the record of the forty years of social welfare which have led to a general belief that people should be saved from the necessity of applying for charity, either private or public. He gives reasons for thinking that we can afford social security. He estimates that, at the most, the country is being asked to set aside an additional part of the national income which will amount, roughly, to the goods and services produced by a half-day's work every three weeks. This estimate should be modified favourably because the new benefits will reduce private spending on doctors' bills, funeral expenses, dentists, etc. He quotes an authority who estimates that if all taxes were suitably adjusted an income tax of 5s. 10d. would fulfil the national needs, as against a pre-war tax of 5s. 6d.

Where the White Paper suggests lower benefits than the Beveridge report he says that this would simply result in more applications for public assistance, and any social security plan worth the name should greatly reduce the need for public assistance. If the State wishes to encourage parenthood it must materially increase the maternity benefits and children's allowances, which he pleads should not be subject to income tax. He comes to the conclusion that there can be no excuse for delaying the introduction of the full plan later than two years after D-Day.

In the only mention of the medical service (on page 106) Mr. Lafitte says that the working of the whole system "would be seriously clogged unless the most vigorous action was taken to build a far better system of health and medical services available to every citizen without fee . . . a system which tolerated no class distinctions . . . and provided for the most rapid extension of hospital, specialist, and medico-social services, and for the raising of general practice to a new level of well-equipped competence by the development of Health Centres." He accuses the late Minister of Health of abandoning many of the most hopeful advances promised in the White Paper "rather than quarrel openly with an obstructionist section of the medical profession, the voluntary hospitals, and the local authorities who thought private trading in medical care, separatism, or parochial prestige more important than the public health." Mr. Lafitte does not attempt to expand this. If he tried to do so, judging from the well-balanced nature of the rest of his book, he would probably have found that the "obstructionist section of the medical profession" could show a pretty good case that in looking after the interests of the profession it had not abandoned its plea for a complete medical service for all who need it, which it had vainly pressed on the attention of the Government years before Sir William Beveridge came on the scene.

APPLIED PHYSIOLOGY

Applied Physiology. By Samson Wright, M.D., F.R.C.P. Eighth edition. Oxford Medical Publications. (Pp. 944; illustrated. 30s.) London: Oxford University Press. 1945.

Prof. Samson Wright is to be congratulated on having produced an eighth edition of his *Applied Physiology* and on having kept it below 1,000 pages. The labour and compression this has required are illustrated by the fact that the *Annual Review of Physiology* for the year 1945 alone comprises 774 pages. "Samson Wright" has become an institution, not merely because it is a good examination textbook, but also because it really is useful to the practising clinician who wishes to understand the mechanism of a particular symptom or disorder. If a criticism may be ventured about so popular a book at this late date, it is as follows: Prof. Samson Wright, like others who discuss the physiological interpretation of symptoms, tells us a great deal about the body in health and in advanced organic disease, but very little about the physiology of the everyday ailments of mankind. The commonest illnesses to-day are upper respiratory infections, rheumatism, and neurosis; but the words nose, joint, and neurosis do not appear in the index of this book. More space is given to the ductless glands than to the whole of the alimentary tract, and in consequence useful conceptions such as the peristaltic gradient and the reverse peristalsis syndrome are not mentioned. Clinical teachers are constantly being urged to tell the student about common diseases and about social medicine, and if their teaching is to have a physiological background the applied physiologist must interest himself more in the common disturbances of the environment and the common diseases.

Notes on Books

Recent Advances in the Chemistry and Biology of Sea Water, by Dr. H. W. HARVEY, summarizes the results of the more recent acquisitions of knowledge relating to the constituents of sea water, with special reference to the nutrition of marine growths. The introductory chapter enumerates the agencies by which the dissolved constituents of sea water are transported, and describes the manner in which these agencies operate. Then follow nine chapters detailing chiefly the findings from the examinations made of the constituents of sea water at different places and at different depths, and the variation of these constituents with varying geographical conditions. Apart from the main constituents of sea water there are elements present in minute traces, some thirty of which have been examined as to their amount. Many of these so-called trace elements exercise a vital function in marine growths. The book contains a valuable discussion of the carbon dioxide system in its relation to alkalinity under different conditions of pressure and other variables. It describes the comparative utilization of nitrogen and phosphorus by plant organisms, and the changes due to bacteria under the influence of light and darkness. These and many other results of research derived from the oceans and from the narrow seas render the book unique and invaluable to all who are concerned with any section of marine biology. The bibliographic references are as exhaustive as they can be made, and give to the book a key position in the literature on the subject. It is published at 10s. 6d. by the Cambridge University Press.

Atmospheric Pollution in Leicester: A Scientific Survey is published for the Department of Scientific and Industrial Research at 3s. by H.M. Stationery Office. During the last twenty-five years a large amount of information has been collected about atmospheric pollution at a few fixed points in each of a number of large towns. This information has been of use in many ways, particularly in indicating whether, over a period of years, the air is generally becoming cleaner or more polluted. But until the observations described in this report were made no one could say with any certainty what were equivalent positions for the measuring instruments or what sort of variations in pollution were to be expected over comparatively short distances within a town. The results at Leicester show that atmospheric turbulence, by carrying down clean air from above and carrying up smoke-laden air from street level, is the most important agent in preventing the accumulation of dirt in the air of our towns and cities. In a short preface the Atmospheric Pollution Research Committee of the Department pays tribute to the way in which Dr. A. R. Meetham and his two assistants carried out this research. The work of the Leicester survey, though partly theoretical, is already having practical consequences.

By the courtesy of the American Library in London we are presented with a copy of a *Symposium on Neuropsychiatric Diseases* reprinted from the *Medical Clinics of North America*, Chicago number (Philadelphia and London: W. B. Saunders Company). This is an unusually interesting collection of papers covering many of the chief subjects of interest to present-day neurologists and psychiatrists. Among the neurological papers are useful discussions on the Guillain-Barré syndrome, the diagnosis and surgical treatment of peripheral nerve injuries, chordotomy for intractable pain, protrusion of the intervertebral disk, and an admirable review of the management of myasthenia gravis including a note on the employment of thymectomy. A paper on periarteritis nodosa suggests that this very interesting disease may be rather more common than hitherto supposed, and that it should always be kept in mind in face of an illness presenting multiple symptomatology, including involvement of the nervous system both central and peripheral. Psychiatric papers deal with the modern concept of schizophrenia, electric shock therapy, insomnia, and the relation of insanity to crime. Other papers on the uses and abuses of quinidine, pernicious anaemia, and the rational endocrine therapy of menstrual disorders will repay study.

Preparations and Appliances

A SUPPORT FOR ANAESTHETIC TUBING

Dr. O. R. Tisdall, honorary anaesthetist, Harrow Hospital, writes:

The corrugated tubes of the Coxeter-Mushin apparatus exert a considerable pull on the face-piece. As it is essential to maintain an air-tight fit in absorption technique, it is evident that this pull should be eliminated if possible.

The apparatus illustrated is practically a retort-stand modified for its purpose, and consists of a clamp which can be fixed to any edge of the operating table, an upright arm, and a horizontal bar which can be revolved to any desired angle and moved to any height. On this is a bar which can be revolved as required, each bar being fixed by a milled-head screw. On the second bar are fixed two clips to carry the tubing. In practice it is found that this will allow of almost any adjustment, and will carry nearly all the weight of the tubing.

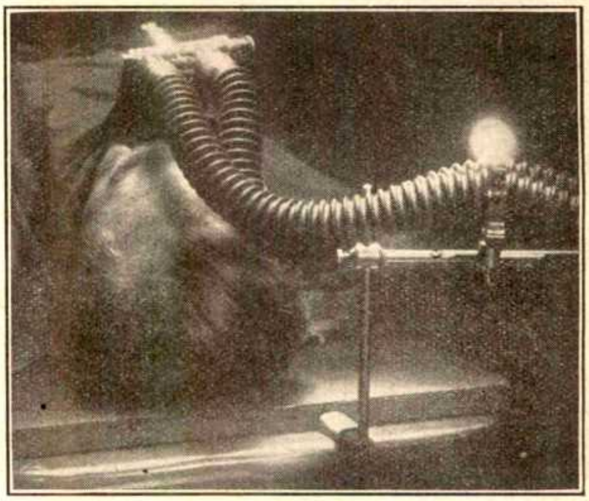

FIG. 1

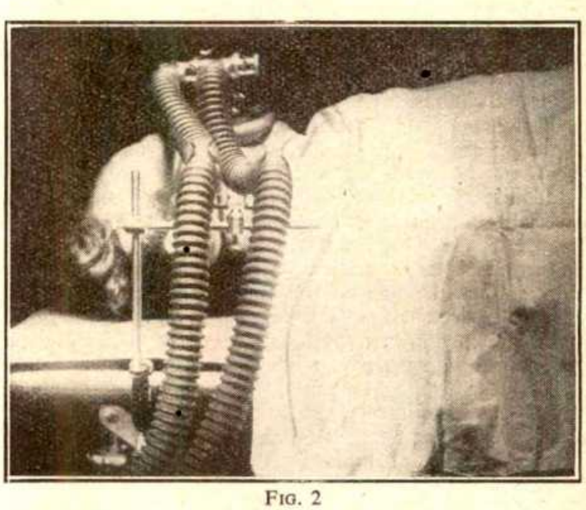

FIG. 2

The model has been kindly made for me by Mr. Dean, of Harrow School Science Laboratories, who is prepared to make a similar model to fit any table.

BRITISH MEDICAL JOURNAL

SATURDAY DECEMBER 29 1945

ELECTROMYOGRAPHY

Severe and sometimes permanent disability results from a peripheral nerve injury, often quite out of proportion to the amount of tissue damaged. Such injuries are particularly noticeable in war, and thus much attention has been given in the last few years to the solution of some of the theoretical and practical problems related to them. Cajal,[1] and more recently Young[2] and Bowden and Gutmann,[3] have shown clearly that the very nature of nerve regeneration is such that complete functional recovery never occurs after total interruption of a nerve. Thus, since recovery from a peripheral nerve interruption must always, in varying degree, fall short of perfection, it is imperative that the exact extent of the lesion should be determined without delay and rational treatment carried out at the optimum time.

Many "diagnostic aids" are already used in connexion with peripheral nerve injuries. The sweating test developed by Guttmann[4] gives valuable information about the functional activity of vasomotor nerve fibres. These fibres, incidentally, travel to their destination in company with the cutaneous nerves, and are therefore involved in any lesion of these nerves. The test can thus give indirect information as to the functional activity of the cutaneous nerves, and is particularly valuable because it is an objective test and does not depend on subjective sensations. Testing the "electrical reactions" of muscles, introduced by Erb,[5] is another useful aid when dealing with motor nerves, but this test depends upon induced activity by external stimuli, and cannot be applied satisfactorily in the case of single "deep" muscles. There have certainly been improvements in technique recently. For instance, Ritchie[6] has devised a stimulator for the routine determination of strength–duration–excitability curves of normal, denervated, and reinnervated muscles, based on the classical galvanic-faradic test. Precise assessment is made possible by stimulating the muscle with a condenser discharge of known voltage, duration, and frequency, these being variable and inconstant with a faradic current. A progressive improvement of excitability is demonstrated during reinnervation, the improvement appearing a short time before the earliest signs of recovery can be detected clinically. This test is a great improvement on previous ones of this nature, but it cannot be used to detect minimal degrees of denervation; and the accurate assessment of denervation or reinnervation in "deep" muscles is still difficult, and in many cases impossible.

The possible value in diagnosis of recording the spontaneous electrical activity of muscles as a whole by means of electrodes either fixed to the overlying skin or inserted directly into the muscles was first reported by Adrian.[7] The work of Denny-Brown and Pennybacker[8] on the electrical activity of denervated muscles was the next notable advance, but it was Weddell and his co-workers[9] [10] who, after extensive investigations of the electrical activity of normal, denervated, and reinnervated muscle, made possible the use of electromyography as a straightforward clinical test. Electromyography is fundamentally different from the electrical reaction test, for it records spontaneous activity as opposed to activity induced by external stimulation. The principles involved are simple, but to understand them one must have a clear idea of the nerve–muscle complex. This is fractionated functionally, not to the ultimate limit of individual muscle fibres but to groups of muscle fibres innervated by one motor neurone, the so-called motor unit. Each of these motor units when activated gives rise to an electrical response which has well-defined properties. However, when the nerve–muscle complex is disorganized by denervation, the muscle fibres which previously contracted in groups now contract individually, and can be seen as scattered intermittent contractions of isolated fibres—a phenomenon termed fibrillation (not to be confused with fasciculation). The electrical activity of these muscle fibres contracting independently of each other can be sharply distinguished from that produced by motor-unit activity. The apparatus for detecting the electrical activity of muscle is robust, simple to use clinically, and all-mains driven. It consists of a co-axial needle electrode connected to an amplifier, a loud-speaker, and a cathode-ray oscilloscope. The latter is employed solely for making permanent records, the differences in frequency and form of action potentials being more easily distinguished by the ear than by the eye. The apparatus also includes a device for passing stimuli down the electrode to the point from which recordings are being made: thus the position of the point of the needle can be determined precisely by observing which muscle contracts.

With the aid of the electromyogram the following general facts have been established. No electrical activity can be recorded from voluntary muscle which is completely relaxed. Motor-unit action potentials appear in response to voluntary or reflex contraction, and on insertion of the electrode into the normally innervated muscle (mechanical stimulation). The sounds evoked from the loud-speaker by these action potentials are rather low-pitched, producing a distinct "plop." In sharp contrast, denervated voluntary muscles give rise to repetitive action potentials provided the muscles are at approximately blood temperature. These repetitive fibrillation action potentials are of two types: those evoked by insertion of the needle electrode due to mechanical stimulation, and those which repeat rhythmically. The latter evoke a characteristic sharp click from the loud-speaker, and the repetitive quality is very noticeable. The time-course of fibrillation activity in man has been found to be longer than in experimental animals. Thus, in the limb muscles the onset is from the sixteenth to the eighteenth day, in the facial muscles from the twelfth to the fourteenth day, and in the sacrospinalis muscles from the tenth to the twelfth day. Such action potentials can be obtained from denervated muscles as late as eighteen years from the date of injury. They can also be obtained from partially denervated muscles. The difference in time-course has been proved experimentally to depend upon a metabolic factor. Another important point which should receive emphasis is that in denervated muscles which have received adequate physiotherapy, as judged clinically, fibrillation is vigorous, whereas in untreated denervated muscles fibrillation is feeble; and in fact on occasions no *spontaneous* fibrillation action potentials can be obtained before warming the limb. In cases of reversible ischaemic block, as in Bell's palsy, motor-unit action potentials are always obtained on insertion of the electrode, and it is usual to find a few repetitive motor-unit action potentials which may or may not be under voluntary control. Fibrillation action potentials, however, are absent or very few in number. Action potentials from reinnervated muscles are characteristic and usually highly polyphasic, particularly when reinnervation follows suture of an interrupted nerve.

[10] *Brain*, 1944, **67**, 178.

Electromyography, therefore, can be used in addition to the familiar electrical reactions. It has a number of advantages, among which is the detection of minimal degrees of lower motor neurone denervation. In addition, it is possible to record the electrical activity in denervated muscles, such as those of the larynx, in which the study of electrical reactions is out of the question, and it is of some interest to note that in a case labelled "recurrent laryngeal palsy of unknown aetiology" the diagnosis of arthritis of the crico-arytenoid joint was established by recording action potentials. Weddell and his colleagues do not suggest that electromyography should replace the determination of the electrical reactions by stimulation, but that electromyography is a more delicate method for gauging damage to the lower motor neurone, and is therefore valuable for the accurate assessment of peripheral nerve injuries and in the early stages of diseases affecting the lower motor neurone. Moreover, the detection of fibrillation action potentials is a positive proof of denervation, which is not possible to obtain with other methods. In a section on muscle tone in relation to motor-unit activity as determined with co-axial needle electrodes Weddell and his colleagues confirm that in a completely relaxed muscle no electrical activity can be recorded by the apparatus employed, and suggest that there is no close relation between muscle tone "determined by the resistance experienced when a limb is moved or displaced passively" and the *motor-unit* activity within a muscle. It is true that co-axial needle electrodes are not ideal for the assessment of "muscle tone"; these workers have themselves proved that their useful recording range is limited to a centimetre or so of muscle surrounding the needle-point, and that the fascial sheath of a muscle insulates the electrode from the electrical activity of surrounding muscles. Nevertheless, they are in general agreement with the findings of Hoefer,[11] using surface electrodes, and it seems certain they are correct in their statement.

Weddell and his colleagues give numerous case records illustrating the use of electromyography in many neurological affections—such as facial nerve paralysis, intrinsic laryngeal muscle paralysis, spinal cord injuries and diseases, and sciatica. They have also shown that in the early stages of "motor neurone" disease the electromyographic picture of repetitive motor-unit action potentials uninfluenced by voluntary contraction differs only in degree from that induced by prostigmin in normal muscle. In both cases the action potentials have been proved to originate at the myoneural junction. Repetitive motor-unit action potentials of a similar type, though in minimal numbers, are seen in slowly progressive peripheral nerve lesions resulting from ischaemia. They also appear in so-called "rheumatic nodules." In the latter the pain and spasm are abolished by infiltration of a local analgesic. As a result of these observations it is probable that there is a stage in the course of degeneration of a peripheral motor neurone at which the threshold at the myoneural junction becomes greatly decreased, so that spontaneous contractions occur. This suggests that spontaneous impulses may arise from sensory receptors in cases of slowly progressive degeneration of sensory nerves, though at the moment there is no proof of this. To summarize, it seems clear that electromyography can now be considered as a useful "clinical aid," and that in the field of academic and clinical research it has yet a part to play.

MASS OBSERVATION AND THE BIRTH RATE

The Advertising Service Guild report on Britain and her birth rate[12] is a document which medical men should read carefully, even those who are not very much interested in the dangers of "race suicide." Because of the general interest of the undertaking we shall speak first of the method. The investigators seek to discover what people think or believe about social problems; in the particular case what they think or believe about rearing families, what they themselves mean to do under present conditions, what they would do if conditions changed. We do not intend to overload this article with figures, but, to give some notion of the scope, we mention that of the women interviewed 222 had had a secondary and 565 only an elementary education, that 317 had been married not more than five years, 132 five to ten years, and 288 more than ten years. For the most part the study relates to London.

It is obvious that the value of the results depends on (1) the number of observations, and (2) the skill of the interviewers. When the skill of the interviewer is great then only (1) is involved, and the ordinary tests of statistical "significance" apply; but if the interviewer is unskilful an arithmetical test may greatly understate the precision of his finding. In the "classical" scheme of dice-throwing or drawing counters from a bag the variance *npq* assumes that the experimenter correctly records the number of pips on the dice or the colours of the counters; if owing to bad light or fatigue he is liable to make mistakes the variance will be larger, even if his errors of observation are uncorrelated and random—namely, if, on the average of many trials, he does find *np* for the mean value. We do not know how "Mass Observation" chooses and standardizes its interviewers, but we have no reason to doubt that a suitable technique has been developed. There is, however, one point to be mentioned. Examiners can be standardized by asking them to mark independently the same script, and we know that, even with experienced examiners, the variation is sometimes disconcerting. But at least the script does not change, though the mood of the examiner does, as re-markings sometimes show. But when the scripts are human beings interviewed at different times and in different moods there may be variation; if A's results differ from B's "significantly" it does not inevitably follow that A is the better (or worse) interviewer.

[12] *Britain and Her Birth-Rate.* Published for the Advertising Service Guild by John Murray, 1945, price 21s.

We pass to the results of the inquiry. In the first place it is clear that the "population" of which this selection is typical is not replacing itself, and almost equally clear that if the aspirations of the wives were fulfilled it still would not replace itself. There is no need to go into arithmetical detail, because what is called the factual inquiry will be carried out on a much larger scale by official or semi-official bodies. It is also made probable that the birth rate among badly educated and ill-informed people is higher than among the better-educated. The authors write:

> "Is the sad truth to-day that children are distributed in inverse ratio to knowledge and the ability and desire to assimilate facts? Have we to rely on the improvident and the wishful-thinking for the perpetuation of the race? The question marks must remain. But it is difficult to find any other interpretation which fits all the contradictions which this survey brings to light. The people who are having most children are mainly the people who care least how many children they have, or, at best, are least capable of finding and using means of preventing them. There is no reason to suppose that legislation will alter this pattern fundamentally. It may well accentuate present trends. If it is desirable to perpetuate the 'don't knows' and the 'don't cares' and the 'can't thinks' while the others gradually become extinct, well and good. Let's get ahead with numbers, and to hell with eugenics.
>
> "But if we want quality as well as quantity, then the aim must be to stimulate the desire for more children where the desire and ability to limit families is most firmly established. Minds are made up most firmly at present where legislative possibilities are least likely to provide a stimulus. Babies bought on the cheap—or even at cost price—will come primarily from those to whom a little extra means a lot, whether they are bought for cash, goods, services, gardens, crèches, or living space. If legislation can appreciably raise the birth rate by itself, it seems likely to raise it most where it is already highest."

Some older readers of this vivid passage will murmur—"Karl Pearson." His style was vivid, if in a slightly different way. Some younger readers will whole-heartedly accept the last sentence of the first paragraph. It is a matter of ideology. An editorial article should be impartial, but, being written by a human being, an unconscious ideological bias is hard to escape. We think that a majority of scientifically educated persons now believe that both Galton and Pearson underestimated the importance of social and familial tradition, as well as other environmental factors, in the production of effective ability in families; we are sure most men believe that an immense amount of ability in the "lower classes" has been stifled by unfavourable environment and that, here particularly, Karl Pearson rather than Galton over-emphasized Nature, perhaps made a false antithesis of Nature and nurture. A favourite analogy of his—that no grindstone can put a fine edge on poor-quality steel—is not really illuminating. But perhaps a majority of biologists still think that Nature (in the Pearsonian sense) is a fundamentally important factor of racial progress, or deterioration, so the passage quoted above merits study.

It would be foolish to pretend that the results of this inquiry give any basis for optimism. This, however, can be said: that few of those interviewed seem to expect the rapid building of a New Jerusalem, so that a sense of frustration may be less widespread than in the years following 1918, particularly as there are no indications of a mirage.

ROLE OF ALLERGY IN DELAYED WOUND-HEALING

The war has stimulated much research into the biological processes involved in tissue repair, particularly into the causes of delayed healing of wounds. The importance of a high protein diet after the initial katabolic phase is now well recognized, and has lately been stressed again in two reviews by Cuthbertson,[1] [2] to whom we are indebted for much of our knowledge of the role of protein and amino-acids in wound repair. Hunt[3] and Bourne[4] have shown that a diet poor in ascorbic acid results in deficient formation of collagen, with lack of tensile strength in skin wounds; and hypovitaminosis C may without doubt be a considerable factor in the delayed healing of wounds. In a small percentage of abdominal wounds actual disruption occurs, and although in most cases the cause may be fairly ascribed to faulty surgical technique, increased abdominal tension, or gross sepsis, there remain a number of instances where none of these factors appears to operate, and in which the protein and vitamin-C levels are well maintained; nevertheless the wound breaks down or heals poorly. To explain this group of cases allergy to catgut has from time to time been put forward as a possible causative factor, and many experimental studies have been made, hitherto with conflicting results.

The subject has been lately reinvestigated in America by Hopps,[5] who shows that, while hypersensitivity to catgut can be produced in rabbits and guinea-pigs, a large amount of this substance must be used over a long period to achieve it: for example, while 700 mg. of powdered catgut administered over one and a half months failed to stimulate the production of humoral antibodies to it, 1,700 mg. given over a six-months period was able to do so. As the latter amount represents a 915-cm. length of size No. 0 plain catgut, it is obvious that the production of a state of allergy requires much perseverance. Furthermore, Hopps found that there was no appreciable difference between normal rabbits and rabbits sensitized to catgut in the rate of dissolution or digestion of catgut during the critical period of healing of wounds, and that catgut-sutured wounds in sensitized rabbits showed no tendency to disruption or delayed healing. These negative findings he attributes to the relative insolubility of catgut sutures, and suggests that in cases where accelerated solution of sutures leads to disruption of wounds some cause other than allergy (e.g., an inflammatory exudate) must be looked for.

[4] *Lancet*, 1944, **1**, 688.
[5] *Arch. Surg.*, 1944, **48**, 438.

Having dismissed sensitivity to catgut as a significant factor in wound-disruption, Hopps postulates a local antigen–antibody reaction within the tissues of the healing wound to explain delayed healing and disruption in cases in which no other obvious cause is in evidence. To confirm this hypothesis he made laparotomy wounds in normal rabbits and in rabbits sensitized to horse serum or crystalline egg albumen. After operation the majority of the sensitized animals were given specific antigen intravenously, the remainder receiving foreign protein other than that to which they had been rendered hypersensitive, while the normal animals received either of the two proteins used in the experiment; by the use of this double control any non-specific effect of the introduction of foreign protein could be determined.

The results were quite striking. Twelve (50%) of the sensitized rabbits receiving specific antigen died of anaphylactic shock. All except one of the remainder of this group exhibited some disturbance of healing, varying from frank separation of the wound layers to local induration, oedema, hyperaemia, and sero-sanguineous exudation. Of the control animals only two showed slight separation of the skin layer over a portion of the wound, and neither in these nor in the other controls was there any significant degree of oedema, hyperaemia, or sero-sanguineous discharge. In the histological examination of biopsy specimens taken from the wounds nine days after operation it was observed that in the case of the sensitized animals which had received specific antigen the reticulum was finer and sparser and there was much less collagen than was found in control animals. But the most significant difference was in the types of "inflammatory" cells present, the ratio of macrophages to fibroblasts being considerably greater in the former group of animals; in some fields directly in the line of incision not a single fibroblast could be seen, though macrophages were abundant. Hopps considers that this failure of the macrophages to mature into fibroblasts is sufficient to account for the structural weakness and consequent disruption of the wounds. But what accounts for the failure of maturation? He suggests that, just as there is concentration of vital dyes at the site of acute "inflammatory" processes, so protein substances (in this case the specific antigens) are actively concentrated in the area of the operation wound, and the local macrophages are stimulated to produce antibodies. "Apparently the incentive to remain macrophages and form antibodies is stronger than the incentive to mature into fibroblasts and form collagen as a process of the healing of wounds."

Hopps admits that the clinical significance of this mechanism is probably not great, but suggests that it may occur when an abdominal operation is done in the face of a well-localized pre-existing infection (e.g., a pelvic abscess), where the patient may be assumed to have a high degree of sensitivity to the specific infectious agent. In such cases operative manipulation of the localized lesion may result in the forcing of bacterial products through the protective granulation tissue into the general circulation; these antigens then concentrate at the site of the operation wound, and stimulate the local macrophages to manufacture antibodies, thus causing delayed fibroplasia and disruption of the wound. Hopps emphasizes the need for thorough reinforcement of such abdominal wounds with non-absorbable sutures and abdominal binders to maintain their mechanical strength longer than is usually necessary.

PASTEURIZATION OF MILK IN ADELAIDE

At a time when profound dissatisfaction is being expressed by medical men in this country over the failure of the Government to realize the hopes raised by Lord Woolton three years ago it is comforting to know that we are not alone in our endeavours to obtain a cleaner and safer milk supply. In an address delivered before the South Australian Division of the Australian Society of Dairy Technology early in this year Dr. A. R. Southwood,[1] chairman of the Central Board of Health of South Australia, makes it clear that the quality of the milk supply in Adelaide, as in other large towns, leaves much to be desired. Dr. Southwood wastes no time in invective: he goes straight to the problem of how to put things right. In his "fourteen points for a peacetime plan" he outlines a series of proposals which, if adopted, would go a long way towards putting milk on the same satisfactory footing in Adelaide as water and meat. He believes—and with this belief we heartily agree—that the milk problem must be treated as a whole. To ensure this he proposes the establishment in each city of a board of control called the Metropolitan Milk Board. This would consist of a chairman, two representatives of "consumers," two "industry" representatives, and one representative of each of the Departments of Health and of Agriculture. The function of the Board would be to exercise complete control over the four major branches of milk supply: production, transport, treatment, and distribution. The Board would insist on the regular veterinary inspection and tuberculin-testing of all cows supplying milk to the city; on proper cleansing and sterilization of utensils on the farm, and on adequate cooling of the milk; on control of the health of the dairymen handling the milk; on the provision of special vehicles to ensure that the milk is kept below 50° F. during transit; on compulsory pasteurization under thoroughly supervised conditions; on the filling of the milk into sterilized bottles with mechanically fitted caps; on the distribution in vehicles designed to keep it cold; on the use of a methylene-blue test for controlling the bacterial cleanliness of the milk before pasteurization, and of a phosphatase test to control the adequacy of the heat treatment; and on the general education of farm and dairy personnel in the hygienic production and care of milk. The South Australian programme is not idealistic, though it would need some modification before being applied to this country. The creation of an independent body to control all stages of milk production, transport, processing, and distribution is an amplification of the proposal for a Permanent Milk Commission put forward by the Milk Reorganization Commission in its 1936 report.[2] The Government has never accepted this suggestion, with the result that these different stages have come more or less under the control of separate bodies, and that no one body is interested in "seeing the milk through" from start to finish.

The health authorities now have little say in the cleanliness of the milk coming into our large towns and cities; this is very largely the business of the Ministry of Agriculture. In spite of the active prosecution during the last three years of a national milk-testing scheme organized by the Ministry it is probably true to say that the bacterial cleanliness of the milk is no higher now than when the scheme came into operation, and is lower than it was before the war. In consequence the large processing firms, which are anxious for their own credit to provide the public with high-quality pasteurized milk, are having to accept milk of such a low standard of bacterial cleanliness that it is no longer possible for them to ensure a good keeping quality for their product.

---

[1] *Med. J. Austral.*, 1945, 1, 454: "Safe Milk for a City. Fourteen Points for a Peacetime Plan." Inaugural address before the South Australian Division of the Australian Society of Dairy Technology, at Adelaide, Jan. 25, 1945.

[2] *Milk.* Report of Reorganization Commission for Great Britain. Min. Agriculture and Fisheries, Economic Series, 1936, No. 44. H.M.S.O., London.

We hope that the new Minister of Health, in his search for a solution of the milk problem, may consider the proposal to appoint one representative body to supervise all aspects of the milk supply, so that this important constituent of our dietary shall be no longer left to the multiple hazards to which it is now exposed.

COLD AGGLUTININS

The presence of cold agglutinins in the serum of cases of primary atypical pneumonia was first reported by Maxwell Finland and his colleagues at the Boston City Hospital in 1943. Their detection was originally due to anomalous findings in attempting to ascertain the blood group of two such patients who developed a haemolytic anaemia. Finland and his colleagues have now published a series of papers[1] describing a systematic study of this phenomenon. The test can be carried out with either plasma or serum from the patient, falling dilutions of which are mixed with an equal volume of a 2% suspension of washed Group O red cells. The tubes are refrigerated overnight, and read after inversion to loosen the deposit of cells. Agglutination varies from a single cohesive mass to fine granularity. Warming to 37° C. for 2 hours completely disperses this form of agglutination.

This test was applied in 211 cases of primary atypical pneumonia, of which the great majority were found to have high cold agglutinin titres, usually over 1 in 80 and sometimes as high as 1 in 2,560 or even more. Repeated tests showed that the agglutinin usually appeared during the second week of the disease. The maximum titre was reached about the beginning of the third week, after which the level fell rather less steeply than it had risen. The test was also performed in 858 other patients suffering from a great variety of conditions: of these, 809 had no significant titre of cold agglutinin, and only 9 had a high one. Three of the 9 were suffering from pneumonia of bacterial origin, 1 from influenza, 1 from tuberculous pleural effusion, and 4 from haemolytic anaemia. The test is therefore rarely positive in conditions other than primary atypical pneumonia, and a high degree of reliance can be placed on it as a diagnostic aid. Other diseases in which positive results have been observed are unlikely to cause confusion: they are trypanosomiasis and tropical eosinophilia.

In their exhaustive study of this reaction from both the technical and the theoretical standpoints the authors have exactly defined its mechanism and significance so far as this is possible without actually identifying the substance responsible. There is a possibility that it is not an agglutinin, but a virus, the reaction corresponding to the Hirst phenomenon—the agglutination of red cells by influenza virus. Its comparative instability tallies with such a hypothesis. On the other hand the fact that most of these sera also agglutinated to a high titre two strains of indifferent streptococci isolated from the lung and sputum of cases of primary atypical pneumonia points rather to an antibody. The association of cold agglutinin with haemolytic anaemia has a peculiar interest of its own. Four out of 7 cases of haemolytic anaemia of various types without pneumonia had high cold agglutinin titres, and 11 of the 211 cases of primary atypical pneumonia developed a haemolytic anaemia; indeed it was in grouping the bloods of 2 of these patients before transfusion that the reaction was discovered. It is quite clear that the agent causing cold agglutination has no haemolytic action, but the possibility is discussed that agglutination in the circulation, taking place perhaps in a chilled peripheral area, may predispose mechanically to lysis. Until this interesting subject is further clarified the test for cold agglutinin might well be employed in obscure cases of haemolytic anaemia as well as in suspected cases of primary atypical pneumonia.

THE SUPPLY OF MIDWIVES

The roll of midwives for England and Wales contains the names of just over 70,000 women, but the number who stated their intention to practise in 1945 is 16,374. This number is an increase on the last four years, and was exceeded only during 1937–40. There are now 2,096 more practising midwives than there were twenty years ago, and the number practising compared with the total number on the roll has gone up in those years by nearly 1%. Of the practising midwives only four now remain who were enrolled as having been in bona-fide practice before the passing of the Midwives Act, 1902, and less than 10% of those now practising were enrolled before 1920. About two-thirds of the midwives are aged between 27 and 47, and only 5.3% are under 27. The register of pupils shows a slight drop for the year. Down to 1935 the number of penal removals from the roll on charges of malpractice, negligence, or misconduct nearly always reached double figures in the year, but of late it has been no more than four, and last year it was only one.

The Central Midwives Board has now approved 97 institutions for the giving of instruction prescribed in the rule on the administration of nitrous oxide and air by midwives, and 2,675 midwives are known to be qualified to give gas-and-air analgesia. The Board has raised again with the Royal College of Obstetricians and Gynaecologists the possibility of amending that part of the rule which requires the presence of a second person at the time of administration, and in the light of a report from the College the Board has been able to amend the rule—a step which it thinks should help to increase the use made of gas-and-air analgesia. Local supervising authorities have been circularized to the effect that a midwife should not administer any drugs of the sulphonamide group except on the specific instructions of a medical practitioner. The Board has agreed to consider sympathetically applications for entry to the midwife-teachers' examination from midwives who gained their post-certificate experience in the Colonies. This has been done on representations from the Rushcliffe Committee on the Training of Nurses in the Colonies. The Board is anxious to do all in its power to help in the improvement of colonial midwifery services.

The Board's report, which is in summary form for reasons of war economy, and relates to the year ended March 31 last, pays tribute to the war service of midwives. "Although they are not to receive any official recognition, not even Defence Medals . . . almost unsung and unhonoured, they perform a public service of prime importance with a devotion which is an example to all."

THE HALF-YEARLY INDEXES

The half-yearly indexes to Vol. I of the *Journal* and the *Supplement* for 1945 have been printed. They will, however, not be issued with all copies of the *Journal* but only to those readers who ask for them. Any member or subscriber who wishes to have one or both of the indexes can obtain what he wants, post free, by sending a postcard notifying his desire to the Accountant, B.M.A. House, Tavistock Square, London, W.C.1. Those wishing to receive the indexes regularly as published should intimate this.

Nova et Vetera

THE EARLY JEWISH CONTRIBUTION TO MEDICINE

The Jews and Medicine: Essays. By Harry Friedenwald, M.D., D.Sc., Professor Emeritus of Ophthalmology in the University of Maryland. Vols. I and II. (Pp. 817; illustrated. $7.50.) Baltimore: The Johns Hopkins Press.

Dr. Harry Friedenwald is one of the most-respected medical men in America. He graduated from Johns Hopkins more than sixty years ago, worked at ophthalmology in Berlin and Vienna, and was long professor of that subject in the University of Maryland. He has attained the highest distinction in his department and served as President of the American Ophthalmological Society. His leisure has always been devoted to historical studies. His generosity with his services, as with the books from his great library, has known no bound. "Such men as Friedenwald," said his friend Osler, "are the true salt of the earth." These volumes contain reprints of 42 articles by him on the relation of the Jewish people to medicine. They are a memorial of which the Johns Hopkins Institute of the History of Medicine is rightly proud.

During the last hundred years, as in several other periods of history, Jews have taken a large share in the development of medicine. For this there are historic, economic, and social reasons. A record of the medical achievements of Jews might be interesting, but this is not Dr. Friedenwald's objective. He is less interested in distinguished Jewish physicians than in their influence as carriers of civilization. Jewish or Hebraic civilization varied in value at different periods. On its investigation Dr. Friedenwald has spent a lifetime. A life's work cannot be reviewed in a short article, but it may be useful to summarize the early Jewish contribution to medicine, mentioning typical figures on whom Dr. Friedenwald has something new to say. The reader must turn to his volumes for detailed reference.

(*a*) *The Biblical and Talmudic period* of Hebrew medicine to about the sixth century A.D. has been comprehensively treated by Preuss. No one is likely to add much to his classical work. The contribution of this period is to have laid the foundation of social and personal hygiene.

(*b*) *Dark Age Hebrew medical literature* is nearly as scanty as Latin. For Hebrew, however, this age begins later and ends earlier. The earliest Hebrew medical text is probably that of Asaph of the seventh (?) century. He had Greek sources and exhibits what is perhaps an elaborated Hippocratic oath. More interesting for cultural contacts is Donnolo (*c.* 913–*c.* 983), a South Italian who wrote in a very peculiar Hebrew dialect. His medical work is the first to show Byzantine, Latin, and Arabic influence. It may thus be said to typify the legend of the school of Salerno as the combined product of the "four masters"—a Latin, a Greek, an Arab, and a Jew.

(*c*) *Early Arabic Medical Literature.*—One of the first scientific works written in Arabic is that of the Egyptian Jew Mashalla (*c.* 750–820)—Messahalla of the Latins. References to his astronomy constantly crop up in mediaeval Latin medicine, and Chaucer based his treatise on the astrolabe on it. Even in Galileo's time it was still being printed. The first Jewish medical author in Arabic was the centenarian Isaac Israeli (855–955) of Kairouan—Isaac Judaeus of the Latins. He founded a regular school of physicians, both Moslems and Jews. His works, and specially his excellent treatise on fevers, continued in general use in Latin until the 17th century. It is often quoted in Burton's *Anatomy of Melancholy* (1621).

(*d*) *The Early Latin translators from Arabic into Latin* provide the first glimmer of intellectual revival in the West. They were largely concerned with medicine, and all worked with Jewish aid. Constantine (*c.* 1020–87) the "African" was perhaps of Jewish origin and certainly relied on Isaac's school. He worked for the Norman Robert Guiscard in Sicily and Salerno, ending at Monte Cassino, where he turned into Latin many medical works, including Isaac's. These continued to be read for centuries. Stephen of Pisa translated in 1127 at Antioch, with Jewish aid, a standard medical work of the Persian Haly Abbas. The most industrious of the translators was Gerard of Cremona (1114–87), who spent fifty years at Toledo. Assisted by Arabic-speaking Jews he rendered the works of many Jewish authors, including Messahala and Isaac.

(*e*) *Early Judaeo-Arabic contacts with the West* were sporadic. We refer to only two. Pedro Alphonsi (1062–1130), an Arabic-speaking Spanish Jew converted to Christianity, came to England early in the 12th century as physician to Henry I. A Latin version by him of an Arabic work written by himself appeared in 1120 and represents the first impact of Arabian learning on this country. Another Spanish Jewish physician who visited England in the 12th century was the philosopher Rabbi ben Ezra (1092–1167), who was in London in 1158. Several of his works appeared in Latin. He was a most romantic figure and his name has become legendary. See Browning's poem "Rabbi ben Ezra."

(*f*) *The great physicians of the 12th century* wrote exclusively in Arabic. Many were Jews. The most famous is Maimonides (1135–1204) of Cordova—Rabbi Moses of the Latins. He ranks high as a philosopher and deeply influenced St. Thomas Aquinas. From 1165 he was very active as a physician at Cairo and has left a pleasing record of the day-to-day medical life of the time. His contemporary Averroes (1126–98) of Cordova was not a Jew but a heretical Moslem much in contact with Jews. His works, including those on medicine, were translated into Latin, not from Arabic but from Hebrew. The same is true of those of his friend Avenzoar (died at Seville 1162). The works of these men, together with those produced by the Italian translators (see *d*), changed the entire character of Western medicine.

(*g*) *Translators from Arabic into Latin in the 13th century* were numerous. Many, perhaps most, were Jews. They worked chiefly in Sicily, Spain, Provence, and North Italy. A name of romance is Michael the Scot (died *c.* 1235). He learned Arabic in Spain, but Roger Bacon says that he did not know it well but was helped by a Jew named Andrew—perhaps Jacob Anatoli (1194–1256) of Marseilles. Michael did great service in issuing the first Latin version of the biological works of Aristotle. It was probably from a Hebrew text. Farradj ben Salim, a Sicilian, was the first professional translator into Latin of Jewish faith. In 1279 he completed the enormous *Liber continens* of Rhazes of Khorasan (died 932), ablest of the "Arab" physicians, for Charles of Anjou (1220–85). This sovereign of the Sicilies had other Arabic-speaking Jews specially trained in Latin to act as translators. Jewish translators were also active in North Italy. Thus the *Colliget* of Averroes was turned into Latin from Hebrew at Padua in 1275, and the *Theisir* of Avenzoar and the *Hygiene* of Maimonides about 1280 at Venice. An extremely popular book was the drug list known as the *Canones generales* of Mesue, which influenced the modern pharmacopoeias. It was originally composed in Hebrew, and was turned into Latin about 1300. About the same time or a few years earlier a similar Hebraeo-Arabic drug list was turned into Latin; probably at Genoa, under the name of Serapion. Mesue and Serapion were printed very many times.

(*h*) *Mediaeval translations into Hebrew of Arabic works* once existed in great numbers. Spanish Jews spoke Arabic and did not need them, but among the Jews of Provence and Italy such knowledge was rare and by the 13th century was fading. The high reputation of Jewish doctors was based on their access to the "Arabian" medical system. Thus Hebrew versions became ever more needed by them as their Arabic knowledge waned. But the new Greek learning of the 15th and 16th centuries rendered the "Arabian" medical system out of date. Hebrew translations thus became useless. The only one to be printed was the huge Canon of Avicenna (Naples, 1491).

(*j*) *Medical Literature of the Spanish Migration.*—Jews were settled in numbers in Spain before the Christian era. The first literary language of the peninsula, other than Latin, arrived with the Saracens. Educated Spanish Jews came to speak and write Arabic. A very rich and varied Jewish literature arose in Arabic, Hebrew, Catalan, and Castilian. The Inquisition and the expulsion of the Jews from Spain in 1492 struck a blow at the Jewish people from which it has probably never recovered. The Spanish Jewish emigrants, however, supplied numbers of distinguished physicians to various parts of Europe for generations. The classic figure of the emigration is Spinoza. In medicine there are, for example, Amatus, whose case-lists are among the earliest of their kind since Hippocrates; Astruc, the syphilographer and founder of Biblical criticism; Brudo, learned in Greek medicine, who visited England; Rodrigo de Castro, who wrote the first scientific gynaecology; Rodrigo de Fonseca, professor of medicine at Pisa in the time of Galileo; Jacob Mantino, a papal physician who played a part in Henry VIII's efforts to divorce Katherine of Aragon; Fernandez Mendes, the first Jewish Fellow of the Royal College of Physicians; Montalto, physician to Marie de Medici; Nostradamus, the "prophet"; Garcia da Orta, the botanist; Pereira, the pharmacologist; Saporta, name of a whole lineage of physicians at Montpellier; Vecinho, adviser of Columbus. And evidence is accumulating that Columbus himself belonged to the stratum of "Marranos" or descendants of forcibly converted Jews.

(*k*) *The Modern Stratum.*—Jewish literature has endured for some 3,500 years. Perhaps its least-esteemed period is from the early 16th to the later 18th century A.D. Apart from the Marranos and their descendants, Jews became unimportant in medicine until the 19th century. But with the liberal movement which followed the French Revolution they began to play a steadily increasing part in medicine. Thus, for example, in Germany the Jews, who formed one per hundred of the population, provided about one in five of the important medical investigators. But this modern contribution has been in no sense "Jewish medicine." It is part of the great "liberal" movement in every other aspect of which Jews have shared. Will the substantial obliteration of Jewish intellectuals in Central Europe and the rise of anti-Semitism elsewhere produce the same prolonged spiritual depression of the Jewish people as did the persecutions of the 15th and 16th centuries? Time alone can show. But the reviewer is inclined to believe that Dr. Friedenwald will have few successors for many generations.

THE FIRST TREATISE ON RICKETS

Three hundred years ago, on Oct. 18, 1645, a medical student aged 26 read at Leyden for the degree of M.D. a thesis entitled *De morbo puerili Anglorum quem patrio idiomate indigenae vocant "The Rickets."* Published in Leyden the same year, this deserves an honoured place among the classics of medicine, being the first printed account of rickets and antedating Glisson's *De Rachitide* by five years. For succinctness and accuracy Daniel Whistler's clinical description could hardly be improved upon (Leonard Findlay). He mentions the softness of the bones, the large head, the narrow chest, the prominent sternum, the swelling of the costo-chondral junctions and of the epiphyses at the wrists, and the distended abdomen. Though his pathology is steeped in speculation, he had boldly shaken off the chains of the humoral theories. Never at any time pretending to have discovered a new disease, he contented himself with introducing a new and unforgivably hideous name—"Paedosplanchnosteocases." Uneasy over the priority of his description being overlooked, Whistler had his thesis reprinted in London shortly before his death, in 1684, from "malignant fever with peripneumony."

A picturesque personality of distinguished charm, to which both Pepys and Evelyn testified, and of facetious wit in which Oliver Cromwell delighted, Whistler was a good physician but a poor poet. According to Munk he took advantage of his position as President to defraud the Royal College of Physicians, though it is not recorded in what precise manner or to what extent. One likes to speculate to what strangely beautiful language the author of *Hydriotaphia* might have been moved by the contemplation of so ironic a fate which immortalized the doubtful aberration of a great clinician, while scattering the poppy of neglect over his masterpiece.

W. R. B.

A correspondent of the *Times* has reported that at a meeting of the Swedish Linné Society, held in the Linnaean Museum at Uppsala, Hr. Anders Grape, chief librarian at Uppsala University, announced the discovery of Linnaeus's manuscript on his contribution to the Swedish Pharmacopoeia, known as the *Materia Medica.* It had been regarded as lost. Those present were given the opportunity of convincing themselves of the genuineness of the document, which was passed round and scrutinized. It is now incorporated in the Linnaeus collections at Uppsala.

Medico-Legal

THE CASE OF A "COCKTAIL TONIC"

A novel kind of prosecution under the Food and Drugs Act, 1938, was heard by justices at Newport Pagnell (Bucks) on Nov. 22, when Vinecta Products, Ltd., of Dewsbury, were summoned for giving a misleading label with a drug described as a "cocktail tonic (non-alcoholic)." The label contained also the words "palatable and invigorating"; and the following formula:

	%
Inf. gent. co.	1·11
Tinct. aurant. aq.	0·084
Ferri et ammon. cit.	0·52
Acid. citric.	0·25
Acid. tart.	0·34
Chlorof.	0·31
Flavouring	q.s.

A half wineglass three times a day was recommended as suitable for children and adults, to be taken before meals.
